# WHO Child Growth Standards 

Growth velocity based on weight, length and head circumference

Methods and development

## WHO Library Cataloguing-in-Publication Data

WHO child growth standards : growth velocity based on weight, length and head circumference : methods and development.

Coordinating team: Mercedes de Onis ... [et al.].
1.Anthropometry - methods. 2.Body size - standards. 3.Child development. 4.Growth. 5.Reference standards. 6.Nutrition assessment. I.de Onis, Mercedes. II.World Health Organization. Dept. of Nutrition for Health and Development.
(NLM classification: WS 103)

## Members of the WHO Multicentre Growth Reference Study Group

## Coordinating Team

Mercedes de Onis [Study Coordinator], Adelheid Onyango, Elaine Borghi, Amani Siyam, Alain Pinol (Department of Nutrition for Health and Development, World Health Organization).

## Executive Committee

Cutberto Garza [Chair], Mercedes de Onis, Jose Martines, Reynaldo Martorell, Cesar G. Victora (up to October 2002), Maharaj K. Bhan (from November 2002).

## Steering Committee

Coordinating Centre (WHO, Geneva): Mercedes de Onis, Jose Martines, Adelheid Onyango, Alain Pinol.

Investigators (by country): Cesar G. Victora and Cora Luiza Araújo (Brazil), Anna Lartey and William B. Owusu (Ghana), Maharaj K. Bhan and Nita Bhandari (India), Kaare R. Norum and GunnElin Aa. Bjoerneboe (Norway), Ali Jaffer Mohamed (Oman), Kathryn G. Dewey (USA).

United Nations Agency Representatives: Cutberto Garza (UNU), Krishna Belbase (UNICEF).

## Advisory Group

Maureen Black, Wm. Cameron Chumlea, Tim Cole, Edward Frongillo, Laurence Grummer-Strawn, Reynaldo Martorell, Roger Shrimpton, Jan van den Broeck. For the work presented in this document, Charlotte M Wright, John Himes, Huiqi Pan, Robert Rigby, Mikis Stasinopoulos and Stef van Buuren, participated in an advisory capacity.

## Participating countries and investigators

Brazil: Cora Luiza Araújo, Cesar G. Victora, Elaine Albernaz, Elaine Tomasi, Rita de Cássia Fossati da Silveira, Gisele Nader (Departamento de Nutrição and Departamento de Medicina Social, Universidade Federal de Pelotas; and Núcleo de Pediatria and Escola de Psicologia, Universidade Católica de Pelotas).

Ghana: Anna Lartey, William B. Owusu, Isabella Sagoe-Moses, Veronica Gomez, Charles SagoeMoses (Department of Nutrition and Food Science, University of Ghana; and Ghana Health Service).

India: Nita Bhandari, Maharaj K. Bhan, Sunita Taneja, Temsunaro Rongsen, Jyotsna Chetia, Pooja Sharma, Rajiv Bahl (All India Institute of Medical Sciences).

Norway: Gunn-Elin Aa. Bjoerneboe, Anne Baerug, Elisabeth Tufte, Kaare R. Norum, Karin Rudvin, Hilde Nysaether (Directorate of Health and Social Affairs; National Breastfeeding Centre, Rikshospitalet University Hospital; and Institute for Nutrition Research, University of Oslo).
Oman: Ali Jaffer Mohamed, Deena Alasfoor, Nitya S. Prakash, Ruth M. Mabry, Hanadi Jamaan Al Rajab, Sahar Abdou Helmi (Ministry of Health).

USA: Kathryn G. Dewey, Laurie A. Nommsen-Rivers, Roberta J. Cohen, M. Jane Heinig (University of California, Davis).

## Acknowledgements

The WHO Child Growth Standards were constructed by the Coordinating Team in the Department of Nutrition for Health and Development of the World Health Organization.

The Study Group is indebted to the parents, children and more than 200 field staff that participated in the WHO Multicentre Growth Reference Study. The generous contribution of many individuals that provided expertise and advice was also crucial to the development of the growth standards.

The project received funding from the Bill \& Melinda Gates Foundation, the Netherlands Minister for Development Cooperation, the Norwegian Royal Ministry of Foreign Affairs, and the United States Department of Agriculture (USDA). Financial support was also provided by the Ministry of Health of Oman, the United States National Institutes of Health, the Brazilian Ministry of Health and Ministry of Science and Technology, the Canadian International Development Agency, the United Nations University, the Arab Gulf Fund for United Nations Development, the Office of the WHO Representative to India, and the WHO Department of Child and Adolescent Health and Development.

## Contents

Executive summary. ..... xvii

1. Introduction .....  1
2. Methodology .....  5
2.1 Design of the WHO Multicentre Growth Reference Study .....  .5
2.2 Anthropometry methods .....  5
2.3 Sample description .....  6
2.4 Data cleaning procedures and correction to target age .....  7
2.4.1 Data cleaning .....  7
2.4.2 Correction to target age .....  7
2.5 Statistical methods for constructing the growth velocity standards .....  8
3. Construction of the weight velocity standards ..... 11
3.1 Weight velocities conditional on age ..... 11
3.1.1 1-month intervals ..... 11
3.1.2 2-month intervals ..... 12
3.1.3 3-month intervals ..... 13
3.1.4 4-month intervals ..... 14
3.1.5 6-month intervals ..... 15
Appendix A3 Diagnostics ..... 34
A3.1a 1-month intervals for boys ..... 34
A3.1b 1-month intervals for girls ..... 40
A3.2a 2-month intervals for boys ..... 46
A3.2b 2-month intervals for girls ..... 52
A3.3a 3-month intervals for boys ..... 58
A3.3b 3-month intervals for girls ..... 61
A3.4a 4-month intervals for boys ..... 64
A3.4b 4-month intervals for girls ..... 70
A3.5a 6-month intervals for boys ..... 76
A3.5b 6-month intervals for girls ..... 82
3.2 Centile tables of weight velocity by birth weight category from birth to 60 days ..... 88
4. Construction of the length velocity standards ..... 93
4.1 2-month intervals ..... 93
4.2 3-month intervals ..... 94
4.3 4-month intervals ..... 95
4.4 6-month intervals ..... 96
Appendix A4 Diagnostics ..... 114
A4.1a 2-month intervals for boys ..... 114
A4.1b 2-month intervals for girls ..... 120
A4.2a 3-month intervals for boys ..... 126
A4.2b 3-month intervals for girls ..... 129
A4.3a 4-month intervals for boys ..... 132
A4.3b 4-month intervals for girls ..... 138
A4.4a 6-month intervals for boys ..... 144
A4.4b 6-month intervals for girls ..... 150
5. Construction of the head circumference velocity standards ..... 157
5.1 2-month intervals ..... 157
5.2 3-month intervals ..... 158
5.3 4-month intervals ..... 159
5.4 6-month intervals ..... 160
Appendix A5 Diagnostics ..... 174
A5.1a 2-month intervals for boys ..... 174
A5.1b 2-month intervals for girls ..... 180
A5.2a 3-month intervals for boys ..... 186
A5.2b 3-month intervals for girls ..... 192
A5.3a 4-month intervals for boys ..... 198
A5.3b 4-month intervals for girls ..... 204
A5.4a 6-month intervals for boys ..... 210
A5.4b 6-month intervals for girls ..... 216
6. Computation of centiles and z-scores for velocities based on weight, length and head circumference ..... 223
7. Discussion ..... 229
8. Bibliography ..... 235
Appendix B Model specifications of the WHO child growth velocity standards ..... 239
Appendix C Results from analyses related to regression to the mean. ..... 240

## Glossary

| BCPE | The Box-Cox power exponential distribution. <br> The median of the Box-Cox power exponential distribution. |
| :--- | :--- |
| $\boldsymbol{\mu}$ | The approximate coefficient of variation of the Box-Cox power <br> exponential distribution - related to the variance. |
| $\boldsymbol{\sigma}$ | The power of the Box-Cox transformation (to the normal <br> distribution) of the Box-Cox power exponential distribution - <br> related to the skewness. |
| $\mathbf{v}$ | The power exponential parameter of the Box-Cox power <br> exponential distribution - related to the kurtosis. |
| $\boldsymbol{\tau}$ | The power of the age (or starting weight) transformation. |
| $\boldsymbol{\lambda}$ | A constant value (delta) added to weight increments. |
| $\boldsymbol{\delta}$ | A power transformation to the normal distribution. |
| Box-Cox transformation |  |
| The ratio of the standard deviation to the mean. |  |

## BCPE

$\mu$

## Skewness

Standard deviation score (SD) See z-score.
A set of detrended Q-Q plots - plots that compare the distribution of a given set of observations to the normal distribution
The deviation of an individual's value from the median value of reference population (or transformed to normal distribution).

## Executive summary

In 1993, the World Health Organization (WHO) undertook a comprehensive review of the uses and interpretation of anthropometric references. The review concluded that the National Center for Health Statistics (NCHS)/WHO growth reference, which had been recommended for international use since the late 1970s, did not adequately represent early childhood growth and that new growth curves were necessary. The World Health Assembly endorsed this recommendation in 1994. In response, the WHO Multicentre Growth Reference Study (MGRS) was implemented between 1997 and 2003 to develop international growth standards for children below 5 years of age. The MGRS is unique in that it was purposely designed to produce a standard by selecting healthy children from diverse ethnic backgrounds living under conditions likely to favour the achievement of their full genetic growth potential. Furthermore, the mothers of the children selected for the construction of the standards engaged in fundamental health-promoting practices, namely breastfeeding and not smoking. The first set of the WHO Child Growth Standards for attained growth based on length/height, weight and age was released in April 2006. The second complementary set, based on head and arm circumference and subscapular and triceps skinfolds, followed a year later.

A key component in the MGRS design was a longitudinal cohort of children who were examined in a sequence of 21 visits starting at birth and ending at 24 months of age. Such frequently collected and well-controlled data are highly unusual. A principal rationale for the MGRS longitudinal component was to allow for the development of growth velocity standards. The increments on which the velocity standards are based were calculated using the longitudinal sample of 882 children ( 428 boys and 454 girls) whose mothers complied fully with the MGRS infant-feeding and no-smoking criteria and completed the follow-up period of 24 months. The children were measured at birth; at weeks $1,2,4$ and 6; monthly from 2-12 months; and bimonthly in the second year.

On the recommendation of a consultative expert group it was decided to develop velocity standards for the following anthropometric variables: weight (the most commonly used measurement and the most responsive to short-term influences), head circumference (the next most-used measurement in clinical settings), and length (potentially useful since stunting originates in the first two years of life, and early detection of changes in velocity may be beneficial for prevention). It was hypothesized that body mass index (BMI) velocity might be useful in predicting changes leading to extremes of adiposity. However, unreliability in BMI increments is a composite of measurement error from various sources. Moreover, BMI peaks during infancy and then drops through the second year. These characteristics make BMI velocity difficult to interpret, and there is little knowledge of its prognostic utility. Therefore, BMI velocity standards were not developed.

Another recommendation by the consultative expert group on the construction of the velocity curves was to explore other distributions in addition to the one used to construct the attained growth standards (the Box-Cox-power-exponential - BCPE). This investigation was carried out in an effort to identify the most appropriate methodology for handling anticipated negative increments specifically in relation to weight. The findings favoured the application of the BCPE distribution with some methodological adjustments only in the case of weight conditional on age. The steps followed to select the best models to fit the data for each indicator were comparable to those used to construct the attained growth standards.

Before the BCPE could be applied to the weight increments conditional on age, it was necessary to add a constant value, delta, to all weight increments to shift their distribution above zero. Afterwards, the predicted centiles were shifted down by the pre-added delta. By the MGRS design, the latest 3-month increment that could be calculated based on observed measurements was from age 11 to 14 months. The 3 -month velocities were constructed for the full age range (birth to 24 months) using the parameter curves estimated for the 2 -month (birth to 24 months), the 3 -month (birth to 14 months) and the 4 -month (birth to 24 months) intervals jointly in a cubic spline surface. All velocity standards required the modelling of skewness. In the interest of keeping the $z$-score calculation formula simple and considering the fact that adjustment for kurtosis had negligible impact on the final predicted
centiles, it was decided not to fit kurtosis (i.e. models were restricted to the LMS class). The diagnostic tools used iteratively to detect possible model misfits and biases in the fitted curves included tests of local and global goodness of fit, such as Q-tests and worm plots. Patterns of differences between empirical and fitted centiles were also examined.

Following wide consultation with different potential users of these standards (e.g. paediatric endocrinologists, neonatologists, lactation counsellors, managers of child health programmes, and researchers), the increments presented in this report are those considered to be most useful clinically. The WHO velocity standards for weight are presented as $1-\mathrm{mo}$ increments from birth to 12 months, and as 2 - to 6 -month incements from birth to 24 months. In addition, weight increments are presented from birth to 60 days in 1 -week and 2-week intervals that coincide with the measurement schedule in the MGRS. The velocity standards for length are presented in 2- to 6-month increments from birth to 24 months. For head circumference, 2- and 3-month increments are presented from birth to 12 months, and 4 - and 6 -month increments from birth to 24 months. One-month increments for length and head circumference were not considered clinically useful as the measurement error over such a short period exceeds the $5^{\text {th }}$ centile as early as 6 months of age. For similar reasons, the 2 - and 3 -month increments for head circumference go up to 12 months of age only. The overall choice of intervals is in line with those proposed by other authors. Electronic copies of the full set of velocity standards are available on the Web: www.who.int/childgrowth/en.

The intrinsic biological complexity of the dynamics of human growth makes the use and interpretation of the standards presented in this report more challenging than that of the attained growth standards. Growth progresses at a rapidly decelerating rate from birth, reaching a near-plateau by the end of the first year, and continues to taper off gently through the second year. This is the expected overall pattern of growth under conditions of adequate nutrition and psychosocial care. However, growth velocities of individual children are characterized by very high variability in consecutive growth intervals. It is not unusual for a child to grow at the $95^{\text {th }}$ velocity centile one month and at the $20^{\text {th }}$ the next while continuing to track on the attained weight-for-age chart. Correlations between subsequent increments are typically low; this reflects both a natural pattern of saltatory growth and possible catchup or catch-down growth that contributes to overall narrowly canalized patterns in the attained growth trajectories of individual children.

The 1-, 2-, 3-, 4- and 6-month increment tables are independent of each other and the clinician should use the one that most closely approximates the interval over which the child is seen. For example, the centile corresponding to an increment between age 2 and 3 months is not associated with the centile corresponding to half of the increment in the 2 -month interval between ages 1 and 3 months. This is because one cannot expect the growth rate in a given 2 -month period, except perhaps at the median, to be the sum of the two corresponding 1-month intervals. With specific reference to weight, negative increments, which generally occur after 6 months of age, are captured in the lowest centiles. They coincide with the weaning period, when children are more exposed to food contamination, and when they become more active and start to explore their environment.

The tables of weight velocity from birth to 60 days present physiological weight losses that occur in the early postnatal period but are not usually included in available reference data. It was not possible to estimate from these data precisely when infants should recover their birth weight following weight loss that is common in the first few postnatal days. Net increments at the median ( 0 to 7 days) are positive for both boys and girls, suggesting that recovery of birth weight could be achieved in less than one week. Considering the $25^{\text {th }}$ centile ( 0 g increment from birth to 7 days), the data suggest that $75 \%$ of newborns recover their birth weight by day 7. It is understood that recovery depends on what percentage of birth weight was lost and the successful initiation of lactation. However, rather than focus only on weight gain, it is important to adopt a holistic approach that looks at the child's overall health status and clinical signs, which are key to maintaining successful infant nutrition. This includes also assessing mother-child interaction, indicators of successful breastfeeding such as infant breastfeeding behaviour and the timing of stage II lactogenesis, and breastfeeding technique. Centiles are presented for both net increments and velocity in $\mathrm{g} / \mathrm{d}$. When mother-child dyads experience
breastfeeding difficulties in the early postpartum period, lactation performance and weight gain are monitored every few days, hence increments per day are likely to be handier to use than weekly or fortnightly increments. However, even in the absence of such difficulties, visits to the clinic take place at random ages, and these daily increments offer a flexible option for evaluating growth over fractions of the tabulated time blocks.

Measurements of growth are subject to error from multiple sources. Faulty measurements can lead to grossly erroneous judgements regarding a child's growth. The accuracy of growth assessment is improved greatly if measurements are replicated independently and the values averaged. Although the high level of reliability achieved in the MGRS is unlikely to be reached in routine clinical measurement in primary health care settings, measurements need to be taken with reasonable care and accuracy as the calculation of increments involves two measurement errors.

Ideally, velocity assessment should be done at scheduled visits that coincide with the ages and intervals (1, 2, 3, 4 and 6 months) for which the centiles are presented. In practice, however, the timing of clinic visits is dictated by uncontrollable factors, and ingenuity will be called for in applying the standards. The discussion section of the report provides overall guidance on interpreting increments that are beyond the allowable range of variation around the intervals, or observed intervals that are on target (say exactly 2 months) but with starting and ending ages that do not coincide with those tabulated in the standards.

There are some fundamental differences between velocity and attained (distance) growth that affect how the increment standards should be used and interpreted. Chief among them is the lack of correlation between successive increments in healthy, normally growing children. For individual attained growth curves, the variability in successive z -scores tends to be minimal over short periods (there are high correlations between successive attained values). This "tracking" is not usually seen for successive individual growth velocities. In the WHO standards, the probability of two consecutive 1 -month or 2 -month weight increments falling below the $5^{\text {th }}$ centile is $0.3 \%$. If the $15^{\text {th }}$ centile is chosen, this probability increases to only $2 \%$ and $1.8 \%$, respectively. Normally growing children can have a very high z -score one month and a very low one the following month, or vice versa, without any underlying reason for concern. Thus, a single low value is not informative; only when velocities are repeatedly low should they cause concern. Nevertheless, very low z-score values, even if observed only once, should raise the question of whether there is underlying morbidity within the holistic clinical assessment of the child.

During periods of severe illness (e.g. prolonged diarrhoea) one would expect very low velocity followed by compensatory high velocity (catch-up). During catch-up growth, one would expect successive increments to be repeatedly in the higher ranges. An important difference with attained growth is that single extreme values of increments are comparatively less worrisome. Ultimately, growth velocity must always be interpreted in conjunction with attained growth, since the position on the attained growth chart is essential to interpreting the growth rate.

The velocity standards presented in this report provide a set of tools for monitoring the rapid and changing rate of growth in early childhood. Future research will need to determine what patterns of successive velocity thresholds over which specified intervals have the best diagnostic and prognostic validity for specific diseases.

## 1. INTRODUCTION

The WHO Multicentre Growth Reference Study (MGRS) was implemented between 1997 and 2003 to develop growth standards for children below 5 years of age. The MGRS collected primary growth data and related information from 8440 healthy breastfed infants and young children from diverse ethnic backgrounds and cultural settings (de Onis et al., 2004a). The first set of the WHO Child Growth Standards based on length/height, weight and age that describe the attained growth of healthy children was released in April 2006. The second complementary set, based on head and arm circumference and subscapular and triceps skinfolds, followed a year later (WHO Multicentre Growth Reference Study Group, 2006a; 2007). The standards are based on a prescriptive approach using well-defined criteria, rigorous data-collection methods, sound data-management procedures, and state-of-the art statistical methods (de Onis et al., 2004b; Borghi et al., 2006).

A key component in the MGRS design was a longitudinal cohort of children who were examined in a sequence of 21 visits starting at birth and ending at 24 months of age. Such frequently collected and well-controlled data are highly unusual, especially given the study's rigorous inclusion criteria (de Onis et al., 2004b). A principal rationale for the MGRS longitudinal component was to allow for development of velocity growth standards.

Proponents of the use of growth velocity consider it a superior quantitative measure of growth compared to attained size for age (Tanner, 1952; Roche and Himes, 1980; Baumgartner et al., 1986; Guo et al., 1991). They point out that, whereas pathogenic factors affect growth velocity directly, their impact on attained size becomes evident only after the altered rate of growth has had time to produce its result (Tanner, 1952). In other words, examining velocity should lead to earlier identification of growth problems than would the examination of attained growth only. Despite their hypothesized advantage, there are far fewer velocity references than there are for attained growth, in part due to scarcity of appropriate longitudinal datasets.

This report presents the WHO growth velocity standards and describes the methods used to construct the standards for weight conditional on age, weight conditional on age and birth weight, length conditional on age, and head circumference conditional on age. Strictly speaking, velocity is a change in value expressed in units per time period (e.g. g/time), while an increment is a change in value expressed in units (e.g. grams). Nevertheless, since the increments presented in this report refer to specific time periods (i.e. 1- to 6 -month intervals), the terms velocity and increment will be used interchangeably.

As part of the preparatory work for the construction of the standards presented in this report, an advisory group met in March 2007 to review uses of growth velocity standards in clinical practice, public health programmes, and research settings and to discuss available strategies and related methods for the construction of the velocity standards. Two background documents were prepared to guide the advisory group's discussions, one on technical and statistical issues (Himes and Frongillo, 2007) and another on the presentation and application of such standards (Wright, 2007).

Among technical issues discussed, the first was whether to model increments (i.e. using measurements) or changes in z -scores. The complexity in applying growth velocity using available presentation formats associated with the z -score scale was recognized.

The second technical issue concerned which approach to statistical modelling to use for the increments, i.e. GAMLSS (Rigby and Stasinopoulos, 2005) or multi-level (ML) (Goldstein, 1986) modelling. The consensus was in favour of GAMLSS over ML modelling because it had been used more extensively in growth curve construction and its capabilities and associated diagnostic tests were better understood. Multi-level modelling was believed to be potentially extremely complex given the large number of growth intervals in the WHO standards data that would have to be modelled. In addition, use of the GAMLSS method as recommended by the background document on statistical issues (Himes and Frongillo, 2007) provided consistency with the methodology used to construct the WHO attained growth standards. Technical aspects regarding presentation and application included the choice of
variables and intervals, and whether data should be displayed as tables or curves. The need for guidance on the use and interpretation of velocity standards was also recognized. It was decided to develop velocity standards for the following anthropometric variables: weight (the most commonly used measurement and the most responsive to short-term influences); head circumference (the next most-used measurement in clinical settings, mainly by neonatologists and others caring for infants); and length (potentially useful since stunting originates in the first two years of life, and detecting changes in velocity during this period may be beneficial in terms of prevention). It was hypothesized that BMI velocity might be useful in predicting changes leading to extremes of adiposity. However, unreliability in BMI increments is a composite of measurement error from various sources. Moreover, BMI peaks during infancy and then drops through the second year. These characteristics make BMI velocity difficult to interpret, and there is little knowledge of its prognostic utility. Therefore, BMI velocity standards were not developed. The final choice of variables (weight, length and head circumference) is similar to other published velocity references (Falkner, 1958; Tanner et al., 1966a, 1966b; Roche and Himes, 1980; Tanner and Davies, 1985; Baumgartner et al., 1986; Roche et al., 1989; Guo et al., 1991; van't Hof et al., 2000).

When selecting measurement intervals, account should be taken of the fact that the calculation of increments involves two measurement errors; hence data are usable only if the measurements are taken with reasonable care and accuracy. Measurement intervals should be wide enough that expected growth exceeds measurement error (Tanner, 1952; Cole, 1995; Himes, 1999). In some cases, velocity reference data (conditional on age) have been presented in yearly intervals (Tanner et al., 1966a; 1966b; Prader et al., 1989), usually from early childhood to early adulthood. However, such intervals cannot be used to detect nascent growth problems with a view to initiating timely corrective action. Falkner (1958) presented reference data for length, weight and head circumference in intervals ranging from three months in the first year to six months in the second year, and one interval from age 2 to 3 years. Baumgartner et al. (1986) published data for 6-month increments from birth to 18 years. Roche et al. (1989) presented centiles of monthly weight and length increments from the Fels Longitudinal sample (birth to 12 months). Two years later, Guo et al. (1991) published reference values of $\mathrm{g} / \mathrm{d}$ or $\mathrm{mm} / \mathrm{d}$ in variable ( $1-$ to 3 -month) intervals. Following wide consultation with potential users of these standards (e.g. paediatric endocrinologists, neonatologists, lactation counsellors, managers of child health programmes, and researchers), the increments presented in this report are those considered to be the most useful clinically.

The WHO velocity standards for weight are presented in two output types. The main output concerns increments conditional on age, presented as 1-month intervals from birth to 12 months, and in 2- to 6month intervals from birth to 24 months. The second output presents empirical centiles of increments from birth to 60 days in 1-week and 2-week intervals that coincide with the measurement schedule in the MGRS: birth to 7 days, and $7-14,14-28,28-42$ and $42-60$ days. These data are presented both as net increments in grams and as $\mathrm{g} /$ day velocities over each index period. It is expected that they will be especially useful for lactation management purposes during this critical period for establishing breastfeeding.

The velocity standards for length are presented in 2- to 6-month increments from birth to 24 months. For head circumference, 2- and 3-month increments are presented from birth to 12 months, and 4 - and 6 -month increments from birth to 24 months. We did not consider 1-month increments for length and head circumference to be clinically useful as the measurement error over such a short period exceeds the $5^{\text {th }}$ centile as early as 6 months of age. For similar reasons, the 2-and 3-month increments for head circumference go up to 12 months of age only. The Technical Error of Measurement (TEM) in the longitudinal study of the MGRS was 0.38 cm for length and 0.24 cm for head circumference (WHO Multicentre Growth Reference Study Group, 2006b). Growth standards should allow for low velocities (e.g. $5^{\text {th }}$ centile) to be detected with some certainty if they are to be clinically useful in detecting growth problems. The overall choice of intervals is supported by approaches suggested by other authors (Himes, 1999).

An important consideration regarding the presentation of standards relates to whether centiles are presented as curves or tabulated values. Curves for attained growth are commonly used to track individual growth patterns, but they cannot serve an equivalent purpose for growth velocity. High levels of intra-individual variation in velocity are normal, and it is not unusual for an infant whose increment at one interval was on the $5^{\text {th }}$ centile to gain at the $75^{\text {th }}$ centile during the next interval. Correlations between subsequent increments are typically low, reflecting a natural pattern of saltatory growth (Lampl et al., 1992) as well as possible catch-up or catch-down growth that contribute to overall narrowly canalized patterns in attained growth trajectories of individual children. For users habituated to attained growth curves, the interpretation of velocity curves presents a counter-intuitive logic: children are not expected to track on a fixed velocity curve (Healy et al., 1988) except perhaps in the median range (Tanner et al., 1966b). For example, a child whose weight velocity tracks on the $3^{\text {rd }}$ centile from 5 to 16 years of age would be lighter at 16 years than a 5 year-old (Baumgartner et al., 1986). On the other hand, a child following the $97^{\text {th }}$ centile from pre-school age would, by maturity, be pathologically enormous (Tanner et al., 1966b).

The lack of correlation between increments makes it difficult to define what constitutes a normal or abnormal sequence of increments, leading to the recommendation that velocity be examined always in conjunction with related measures of attained growth (Tanner, 1952). Different variants of charts combining the concepts of attained size and velocity have been developed and proposed for clinical use, particularly in the United Kingdom (Wright et al., 1994; Cole, 1997; Cole, 1998; Wright et al., 1998). However, those tools do not appear to have gained currency even when incorporated into computerized applications.

The models used in developing the WHO growth velocity standards produce centiles on a continuous scale, but the final centile values are presented in tabular format only for the specific age intervals described earlier. Graphic diagnostic outputs with point estimates linked as curves (not model-based curves) are presented throughout the report to facilitate comparisons between fitted and empirical centiles. Electronic copies of the full set of velocity standards are available on the Web: www.who.int/childgrowth/en. These standards provide a set of tools for monitoring the rapid and changing rate of growth in early childhood.

## 2. METHODOLOGY

### 2.1 Design of the WHO Multicentre Growth Reference Study

The MGRS (July 1997-December 2003) was a population-based study undertaken in Davis, California, USA; Muscat, Oman; Oslo, Norway; and Pelotas, Brazil; and in selected affluent neighbourhoods of Accra, Ghana and South Delhi, India. The MGRS protocol and its implementation in the six sites are described in detail elsewhere (de Onis et al., 2004a). Briefly, the MGRS combined a longitudinal component from birth to 24 months with a cross-sectional component of children aged 18-71 months. The longitudinal sample with visits planned at target ages allowed for the construction of growth velocity standards, which are the focus of this report. Mothers and newborns were screened and enrolled at birth and visited at home a total of 21 times on weeks $1,2,4$ and 6 ; monthly from 2-12 months; and bimonthly in the second year. Data were collected on anthropometry, motor development, feeding practices, child morbidity, perinatal factors, and socioeconomic, demographic and environmental characteristics (de Onis et al., 2004b).

The study populations lived in socioeconomic conditions favourable to growth where mobility was low, $\geq 20 \%$ of mothers followed WHO feeding recommendations and breastfeeding support was available (de Onis et al., 2004b). Individual inclusion criteria were: no known health or environmental constraints to growth; mothers willing to follow MGRS feeding recommendations (i.e. exclusive or predominant breastfeeding for at least 4 months, introduction of complementary foods by the age of 6 months, and continued partial breastfeeding up to at least 12 months); no maternal smoking before and after delivery; single term birth; and absence of significant morbidity (de Onis et al., 2004c).

As part of the site-selection process in Ghana, India and Oman, surveys were conducted to identify socioeconomic characteristics that could be used to select groups whose growth was not environmentally constrained (Owusu et al., 2004; Bhandari et al., 2002; Mohamed et al., 2004). Local criteria for screening newborns, based on parental education and/or income levels, were developed from those surveys. Pre-existing survey data for this purpose were available from Brazil, Norway and the USA. The enrolment and baseline characteristics of the WHO Multicentre Growth Reference Study are described in detail elsewhere (WHO Multicentre Growth Reference Study Group, 2006c).

Term low-birth-weight ( $<2500 \mathrm{~g}$ ) infants ( $2.3 \%$ ) were not excluded. Since it is likely that in well-off populations such infants represent small but normal children, their exclusion would have artificially distorted the standards' lower centiles.

### 2.2 Anthropometry methods

Data collection teams were trained at each site during the study's preparatory phase, at which time measurement techniques were standardized against one of two MGRS anthropometry experts. During the study, bimonthly standardization sessions were conducted at each site. Once a year, the anthropometry expert visited each site to participate in these sessions (de Onis et al., 2004c). Results from the anthropometry standardization sessions have been reported elsewhere (WHO Multicentre Growth Reference Study Group, 2006b). For the longitudinal component of the study, screening teams measured newborns within 24 hours of delivery, and follow-up teams conducted home visits until 24 months of age (de Onis et al., 2004b).

The longitudinal component of the MGRS included data on weight, recumbent length (referred to subsequently as length) and head circumference, for which growth velocity standards are presented in this report. Observers working in pairs collected anthropometric data. Each observer independently measured and recorded a complete set of measurements, after which the two compared their readings. If any pair of readings exceeded the maximum allowable difference for a given variable (weight, 100 g ; length, 7 mm ; head circumference, 5 mm ), both observers once again independently measured and recorded a second and, if necessary, a third set of readings for the variable(s) in question (de Onis et al., 2004b).

All study sites used identical measuring equipment. Instruments needed to be highly accurate and precise, yet sturdy and portable to enable them to be carried back and forth on home visits. Length was measured with the portable Harpenden Infantometer (range $30-110 \mathrm{~cm}$, with digit counter readings precise to 1 mm ). Portable electronic scales with a taring capability, calibrated to 0.1 kg (i.e. UNICEF Electronic Scale 890 or UNISCALE), were used to measure weight. A self-retracting, 0.7 cm -wide, flat metal tape with a blank lead-in strip (calibrated to 1 mm ), was used to measure head circumference. Metal tapes were chosen because they are robust and accurate, and stay in a single plane around the head. They were replaced on a regular basis when the grading marks faded. Length and head circumference were recorded to the last completed unit rather than to the nearest unit. To correct for the systematic negative bias introduced by this practice, 0.05 cm (i.e. half of the smallest measurement unit) was added to each measurement before analysis. This correction did not apply to weight, which was rounded off to the nearest 100 g . Full details of the instruments used and how measurements were taken are provided elsewhere (de Onis et al., 2004c).

### 2.3 Sample description

A total of 1743 children were enrolled in the longitudinal sample, six of whom were excluded for morbidities affecting growth (4 cases of repeated episodes of diarrhoea, 1 case of repeated episodes of malaria, and 1 case of protein-energy malnutrition) leaving a sample of 1737 children ( 894 boys and 843 girls). Of these, the mothers of 882 children ( 428 boys and 454 girls) complied fully with the MGRS infant-feeding and no-smoking criteria and completed the follow-up period of 24 months ( $96 \%$ of compliant children completed the 24-month follow-up) (Table 1).

Table 1 Total sample and number of compliant children in the longitudinal component

| Site | $\mathbf{N}$ | Compliant $^{\text {a }}$ |  |  |
| :--- | :---: | ---: | :---: | :---: |
|  |  | Boys | Girls | Total |
| Brazil |  | 29 | 37 | 66 |
| Ghana | 328 | 103 | 124 | 227 |
| India | 301 | 84 | 89 | 173 |
| Norway | 300 | 75 | 73 | 148 |
| Oman | 291 | 73 | 76 | 149 |
| USA | 208 | 64 | 55 | 119 |
| All | 1737 | 428 | 454 | 882 |
| a Compliant with infant-feeding and no-smoking criteria and completed |  |  |  |  |
| the 24-month follow-up. |  |  |  |  |

Based on the compliant children's data, 1-, 2-, 3-, 4- and 6-month increments were calculated for weight, length and head circumference. For weight, a total of 10184 1-month increments ( 4909 for boys and 5275 for girls), 14410 2-month increments ( 6950 for boys and 7460 for girls), 9294 3-month increments ( 4476 for boys and 4818 for girls), 126904 -month increments ( 6114 for boys and 6576 for girls) and 10999 6-month increments ( 5299 for boys and 5700 for girls) were calculated. Shorter interval increments were also calculated between birth and two months following the MGRS design for use in lactation management programs (see section 3.2). For these shorter intervals, there were 2014 weight increments for boys and 2088 for girls. For length, a total of 14520 2-month increments ( 7016 for boys and 7504 for girls), 9411 3-month increments ( 4545 for boys and 4866 for girls), 12803 4-month increments ( 6183 for boys and 6620 for girls) and 11097 6-month increments ( 5358 for boys and 5739 for girls) were calculated. For head circumference, a total of 14517 2-month increments ( 7005 for boys and 7512 for girls), 94053 -month increments ( 4536 for boys and 4869 for girls), 12807 4-month increments ( 6178 for boys and 6629 for girls) and 11100 6-month increments (5353 for boys and 5747 for girls) were calculated.

### 2.4 Data cleaning procedures and correction to target age

### 2.4.1 Data cleaning

## Weight

Distributions of 1- and 2-month weight increments, not surprisingly, included negative increments (about $4.1 \%$ for the 1 -month and $3.4 \%$ for the 2 -month increments). In most cases, these were associated with reported morbidity and occurred mainly towards the end of Year 1 and in Year 2. Over $99.5 \%$ of negative increments were retained, as they are part and parcel of normal growth. Of the 16403 weight values available, $57(0.35 \%)$ with reported morbidity that entailed losses greater than 250 g per month were set to missing. Four additional weights $(0.02 \%)$ without reported morbidity but with losses greater than 350 g per month in Year 1 or 1 kg per month in Year 2 were also set to missing. The threshold was set at approximately $10 \%$ of the median birth weight for the first year, and at about $10 \%$ of the median weight of a child at 12 months for the second year. In routine paediatric care, large weight losses, even in the absence of reported morbidity, are a sign of underlying problems (sub-clinical illness or psychosocial problems) that normally trigger diagnostic investigations. It is important to note that weights and not increments were excluded, which means that the large negative increments and the usually large positive increments immediately following them were both excluded.

## Length and head circumference

In the case of length and head circumference no values were set to missing.

### 2.4.2 Correction to target age

The actual ages at which the measurements were made were at times delayed (or advanced on a few occasions) compared to the target ages. This resulted in some measurement intervals being either longer or shorter than planned by the MGRS design (e.g. 61 days for a 2 -month interval). The data were corrected to target age as shown in Table 2.

Table 2 Maximum tolerable differences in days between planned and actual measurement ages.

| Age range <br> (months) | Maximum tolerable difference <br> (Diff = Actual measurement age - target age ${ }^{\mathbf{a}}$ ) |
| :--- | :--- |
| $0-6$ | $\pm 3$ days |
| $6-12$ | $\pm 5$ days |
| $12-24$ | $\pm 7$ days |

${ }^{\text {a }}$ Target ages of the MGRS schedule were $0,28,61,91,122,152,183,213$, $244,274,304,335,365,426,487,548,609,670,731$ days

The correction method was applied as follows:

- when the Diff was positive and greater than the tolerable difference indicated in Table 2, the measurement (i.e. weight, length or head circumference) corresponding to the target age was estimated by linear interpolation using measurements at the immediate previous visit and at the actual measurement age corresponding to the interval of interest. For example, if a visit was done at day 100 the weight measurement for the target visit age ( 91 days) was derived by interpolating between the weights at age 61 days and age 100 days.
- when the Diff was negative and greater in absolute value than the tolerable difference indicated in Table 2, the measurement (i.e. weight, length or head circumference) corresponding to the
target age was estimated by linear interpolation using measurements at the actual age corresponding to the interval of interest and the immediate subsequent age that corresponded to the next planned visit. For example, for a visit at age 80 days, the estimated weight for age 91 days was based on weights at ages 80 and 122 days.

The correction to target age was applied to less than $10 \%$ of all measurements. The final numbers of observed increments used in the construction of the WHO child growth velocity standards are shown in Table 3.

Table 3 Number of increments available for the construction of the WHO child growth velocity standards by sex and anthropometric indicator

| Indicator | Interval | Girls | Boys | Total |
| :--- | :--- | :--- | :--- | ---: |
|  | 1-month | 5242 | 4869 | 10111 |
| Weight | 2-month | 7419 | 6889 | 14308 |
|  | 3-month | 4789 | 4440 | 9229 |
|  | 4-month | 6537 | 6058 | 12595 |
|  | 6-month | 5662 | 5247 | 10909 |
|  | 2-month | 7504 | 7016 | 14520 |
| Length | 3-month | 4866 | 4545 | 9411 |
|  | 4-month | 6620 | 6183 | 12803 |
|  | 6-month | 5739 | 5358 | 11097 |
|  | 2-month |  |  |  |
| Head circumference | 3-month | 5316 | 4947 | 10263 |
|  | 4-month | 4869 | 4536 | 9405 |
|  | 6-month | 5747 | 6178 | 12807 |
|  |  | 5353 | 11100 |  |

${ }^{a}$ Number of available head circumference 2-month increments up to 14 months (see Chapter 5).

The fact that visits in the second year took place at 2-month intervals was a limitation when it came to constructing the 3 -month velocity standards. The latest 3 -month increment that could be calculated based on observed measurements was from age 11 to 14 months. The approach proposed to construct 3-month velocities for the full age range (birth to 24 months) was to use the parameter curves estimated for the 2 -month (birth to 24 months), the 3 -month (birth to 14 months) and the 4 -month (birth to 24 months) intervals jointly in a cubic spline surface (described in section 2.5). In the case of head circumference, it was not necessary to apply this approach because the 3-month interval centiles were presented only up to age 12 months.

### 2.5 Statistical methods for constructing the growth velocity standards

The underlying methodology used for constructing the weight, length and head circumference velocity standards was the same used to construct the attained growth standards, i.e. the Box-Cox-powerexponential distribution (BCPE - Rigby and Stasinopoulos, 2004) with a cubic spline smoothing function. The growth curve fitting method and diagnostic tools used to select the best models for each of the indicators are described in detail in the report on the WHO child growth standards (WHO Multicentre Growth Reference Study Group, 2006a; 2007). In sum, the diagnostics included the Qtests (Royston and Wright, 2000) and worm plots (van Buuren and Fredriks, 2001) for local and global goodness of fit. Patterns of differences between empirical and fitted centiles also were examined.

Weight velocities conditional on age required adjustment of the methodology to handle anticipated negative weight increments resulting from weight losses. The BCPE distribution is defined only on positive values. Distributions other than the BCPE were investigated for capability to handle negative increments. The two distributions that could be applied with no restrictions were the Sinh-arcsinh
(SHASH) distribution (Jones and Pewsey, 2008) and the skew exponential power (SEP) distribution (DiCiccio and Monti, 2004). Both distributions are recent methodologies that have not been extensively applied and tested on empirical data. However, both are available for application with the GAMLSS package (Stasinopoulos et al., 2004).

A few trials with the SHASH distribution were carried out using the 2 -month weight increments sample. The modelling proved to be unstable. For example, in using the same approach as applied for the attained growth curves to select the best model, many of the models considered either failed to converge or did so only after 100 or more iterations. For the SEP distribution, also investigated using the 2 -month weight increments sample, models would converge only for low degrees of freedom producing over-smoothed curves that fitted the data badly. Moreover, the SEP distribution requires numerical integration for the calculation of $z$-scores, which cannot be obtained without a computer. This would be a major drawback for the application of the growth velocity standards. Given the operational uncertainties around the application of these distributions and the poor results obtained when they were applied to the MGRS data, the decision was made to revert to the BCPE (which readily simplifies to the LMS method (Cole and Green, 1992) if no adjustment for kurtosis is necessary).

In some cases, there was residual kurtosis after adjusting for the skewness parameter. Conducted comparisons demonstrated that adjusting for kurtosis resulted in very slight shifts in the predicted centiles. In order to avoid having to apply the necessarily complicated resulting z-score calculation formula, the decision was made not to model kurtosis. The velocity data were thus fitted using the LMS method.

Before the BCPE could be applied to these data, it was necessary to add a constant value (termed delta, ) to all weight increments to shift their distribution above zero. The BCPE was swift in fitting the data to predict centiles, which were then shifted downward by the pre-added delta. A similar procedure was applied in constructing the attained growth standards for length/height-for-age (WHO Multicentre Growth Reference Study Group, 2006a). To calculate $z$-scores, the delta value needs to be incorporated into the LMS formula. Delta should first be added to the child's increment and then the $\mathrm{L}, \mathrm{M}$ and S values derived from the model fitted on the shifted observations should be used. When a child's increment is less than (-)delta (i.e. the increment is negative and its absolute value is greater than delta), the correction applied for the skewed attained growth standards beyond -3SD or +3SD applies (such an increment will always lie below -3SD). It was verified that, whereas the modelling process for each of these velocity standards was sensitive to the choice of delta, the final centile curves were practically unaffected and followed the empirical data closely.

For each interval for which the weight increment was modelled, a constant delta value was added at all ages, but it varied by sex for some of the intervals. The delta values were near the absolute value of the minimum observed increment at each interval. In the case of the 1 -month interval, delta was 400 g for both sexes; for the 2 -month interval, it was 600 g for both sexes; for the 4 -month interval, it was 500 g for boys and 800 g for girls; and in the case of the 6 -month interval, it was 350 g for boys and 450 g for girls. Exceptionally, three observed losses in the 4 -month interval data for girls were between 600 g and 700 g . These were the result of smaller losses accumulated in two consecutive 2 -month measurement intervals. Despite their magnitude, these negative increments were not excluded and in each case they were followed by compensatory large increments.

As noted in section 2.4, observed 3-month increments were available only up to 14 months of age. The approach proposed to construct 3-month velocities for the full age range (birth to 24 months) was to use parameter curves (L, M and S) estimated for the 2-month (birth to 24 months), the 3-month (birth to 14 months), and the 4 -month (birth to 24 months) intervals jointly in a cubic spline surface.

The following steps were undertaken:

1. For weight, it was necessary to unify the delta across intervals for each sex ( 650 g for boys and 800 g for girls). The final BCPE model specifications for the 2 - and 4 -month intervals were re-applied to the data but using the unified delta values. For length, the final BCPE parameter estimates for the 2- and 4-month intervals were used.
2. For both length and weight 3-month intervals, the search for the best BCPE model was carried out using only observed increments (i.e. $1-4 \mathrm{mo}, 2-5 \mathrm{mo}, \ldots, 11-14 \mathrm{mo}$ ). To minimize the right edge effect, parameter estimates up to 12 months only were used in the analyses described below.
3. $\mathrm{L}, \mathrm{M}$ and S parameter estimates obtained in steps 1 and 2 were fed into a cubic spline fitting exercise (a surface fitting of the parameter as a function of age and interval) that was done for each of the parameters separately. The exception was the $L$ values for length, which were estimated as constant values for both boys and girls. In this exercise, the ages corresponding to the intervals were shifted to their mid-point. The three parameters were each fitted on transformed age to the power 0.05 and, in addition, the natural logarithm transformation was applied to the S estimates (similar to GAMLSS modelling).
4. The estimation obtained from the cubic splines for each of the $\mathrm{L}, \mathrm{M}$ and S parameters allowed the prediction of the 3-month velocity from birth to 24 months.
5. Finally, the predicted L, M and S values were used to construct the centile curves using the usual LMS formulae (including delta in the case of weight).

The Q-test results were interpreted and considered simultaneously with results of worm plots (van Buuren and Fredriks, 2001). On a few occasions, the two diagnostic tools indicated significant residual skewness for the selected models (e.g. girls' 2-month length velocity conditional on age). Worm plots were examined to detect any misfit of the median or the variance, or remaining skewness. Given that adjustment for kurtosis was never considered, there were some cases where the plots remained depicting non-flat worms (as S-shaped worms). It is worth mentioning that in all cases with significant residual skewness, increasing the number of degrees of freedom used to fit the parameter $v$ did not improve model adequacy. The selection of the model in those cases relied more on the goodness of fit when comparing fitted with predicted $3^{\text {rd }}$ to $97^{\text {th }}$ centiles. In sum, difficulties experienced in finding models of best fit, especially in adjusting for skewness, likely indicate that the smoothing curves cannot fully capture the inherent fluctuations across ages, rather than that the BCPE inadequately fits the increments at each age.

It is worth noting that in the case of velocities conditional on age, the variable age as used in the modelling exercise and subsequent diagnostic outputs refers to age in months at the end of the interval in question. For example, in the case of the 1 -month weight velocity, an increment at age 5 months corresponds to the weight gain between ages 4 and 5 months. Prior to determining the best degrees of freedom for the parameter curves, a search was conducted for the best $\lambda$, the age-transformation power. For this, an arbitrary starting model $\left(\operatorname{BCPE}\left(x=\operatorname{age}^{\lambda}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=4, \tau=2\right)\right)$ was used and the selection was based only on the global deviance values over a preset grid of $\lambda$ values. The GAMLSS package (Stasinopoulos et al., 2004) was used to construct the growth standards.

## 3. CONSTRUCTION OF THE WEIGHT VELOCITY STANDARDS

### 3.1 Weight velocities conditional on age

The objective was to create sex-specific velocity curves for $1-, 2-, 3$-, 4 - and 6 -month weight increments conditional on age. Tables generated from the 1-month increment curves contain estimated centiles for ages $0-1,1-2, \ldots, 11-12$ months; tables generated from the 2 -month increment curves contain estimated centiles for ages $0-2,1-3, \ldots, 22-24$ months; tables generated from the 3-month increment curves contain estimated centiles for ages $0-3,1-4, \ldots, 21-24$ months; tables generated from the 4 -month increment curves provide estimated centiles for ages $0-4,1-5, \ldots, 20-24$ months; and the tables from the 6 -month increment curves provide estimated centiles for ages $0-6,1-7, \ldots$, 18-24 months.

### 3.1.1 1-month intervals

## Boys

There were 4869 1-month weight increments for boys. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\mathrm{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=9$ and $\operatorname{df}(\sigma)=4$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=4$ and the model $\operatorname{BCPE}\left(\mathrm{x}=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=4, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.1a. The Q-test results (Table A3.1) and worm plots (Figure A3.1) from this model indicated residual skewness in only 1 out of 12 age groups. The overall Q-test p-values were all non-significant, indicating an adequate fit of the boys' 1 -month weight increments. Figure A3.2 shows the fitted $\mu, \sigma$ and $v$ curves (dotted blue line) against their corresponding empirical estimates (points in red). There is no evidence of bias in any of the parameters. The next three figures (A3.3, A3.4 and A3.5) show no evidence of bias when comparing fitted against empirical centiles or centile residuals, except for a minor over-estimation of about 20 g in the $50^{\text {th }}$ and $75^{\text {th }}$ centiles.

Table 4 presents the predicted centiles for boys' 1 -month weight velocities between birth and 12 months.

## Girls

There were 5242 1-month weight increments for girls, eleven of which were excluded as outliers, leaving a final sample of 5231 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=13$ and $\operatorname{df}(\sigma)=4$ provided the smallest $\operatorname{GAIC}(3)$. Yet the median fit for that model was under-smoothed compared to that of the boys and decreasing the $\operatorname{df}(\mu)$ to 9 (the same as for the boys) resulted in a smoother curve. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\mathrm{df}(v)=1$ so the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.1b. The Q-test results (Table A3.2) and worm plots (Figure A3.6) from this model indicated adequate fit as the overall Q-test p-values were non-significant at the $5 \%$ level. Figure A3.7 illustrates the fitting of parameters $\mu, \sigma$ and $v$ (dotted blue line) using the final model and their respective empirical estimates (points in red). No bias is observed for any of the parameters. Figures A3.8 and A3.9 show adequate fitting of centile curves.

Figure A3.10 depicts the distribution of the centile residuals, which indicate a slight over-estimation of the $75^{\text {th }}$ centile (average of about 30 g ) but no bias otherwise in any of the remaining centiles.

Table 5 presents the predicted centiles for girls' 1-month weight velocities between birth and 12 months.

### 3.1.2 2-month intervals

## Boys

There were 6889 2-month weight increments for boys, seven of which were excluded as outliers, leaving a final sample of 6882 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=12$ and $\operatorname{df}(\sigma)=6$ provided the smallest GAIC( 3 ). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\mathrm{df}(v)=3$ and the model $\operatorname{BCPE}\left(\mathrm{x}=\operatorname{age}{ }^{0.05}, \operatorname{df}(\mu)=12, \operatorname{df}(\sigma)=6, \operatorname{df}(v)=3, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.2a. The Q-test results (Table A3.3) and worm plots (Figure A3.11) from this model indicated residual skewness in only 1 out of 17 age groups, and the overall Q-test p-values were non-significant at the $5 \%$ level. The fitted curves of the parameters $\mu, \sigma$ and $v$ seemed adequate when compared to the empirical values (Figure A3.12). The fitted centile curves and empirical centiles are shown in figures A3.13 and A3.14. Figure A3.15 shows the distribution of empirical minus fitted centile differences. There appears to be a slight but systematic under-estimation in the $25^{\text {th }}$ centile, averaging about 25 g and countered by an equally slight over-estimation in the $75^{\text {th }}$ centile.

Table 6 presents the predicted centiles for boys' 2 -month weight velocities between birth and 24 months.

## Girls

There were 7419 2-month weight increments for girls, ten of which were excluded as outliers, leaving a final sample of 7409 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=12$ and $\operatorname{df}(\sigma)=5$ provided the smallest GAIC( 3 ). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\operatorname{df}(v)=4$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}{ }^{0.05}, \operatorname{df}(\mu)=12, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=4, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.2b. The Q-test results (Table A3.4) and worm plots (Figure A3.16) from this model indicated residual skewness in only 1 out of 17 age groups and the overall Q-test p-values were non-significant at the $5 \%$ level. Figure A3.17 shows adequate fitting of the parameters $\mu, \sigma$ and $v$ with the respective sample estimates. Similar to the boys, comparisons between fitted and empirical centiles and centile residuals depict patterns of underestimation ( $25^{\text {th }}$ centile) and over-estimation ( $75^{\text {th }}$ centile) of about 25 g (Figures A3.18 to A3.20).

Table 7 presents the predicted centiles for girls' 2 -month weight velocities between birth and 24 months.

### 3.1.3 3-month intervals

## Boys

There were 4440 3-month weight increments for boys, three of which were excluded as outliers, leaving a final sample of 4437 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=3$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\operatorname{df}(v)=1$ but $\operatorname{df}(v)=2$ yielded very similar $\operatorname{GAIC}(3)$ value and allowed the $v$ curve to closely follow the patterns observed for the 2 - and 4 -month intervals. Thus, for the benefit of jointly modelling parameter curves for the three intervals, the model $\operatorname{BCPE}\left(x=\right.$ age $^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=3$, $\operatorname{df}(v)=2, \tau=2$ ) was selected to predict the boys' 3-month interval parameter curves up to age 12 months (see step 2 in section 2.5).

Those parameter estimates were joined to their equivalents obtained from the 2- and 4-month interval models (birth to 24 months) using the unified delta value ( 650 g ) and a cubic spline surface was fitted for each parameter (L, M and S). The resulting predicted parameter estimates for interval 3-months (birth to 24 months) were used to construct the final centiles for boys.

The diagnostic results are presented in Appendix A3, section A3.3a. Figures A3.21 to A3.23 show minor bias ( 25 g on average) in the $10^{\text {th }}$ and lower centiles (under-estimation) and a slight overestimation in the $75^{\text {th }}$ and $90^{\text {th }}$ centiles (less than 50 g on average).

Table 8 presents the predicted centiles for boys' 3-month weight velocities between birth and 24 months.

## Girls

There were a total of 4789 3-month weight increments for girls, seven of which were excluded as outliers, leaving a final sample of 4782 observations for the modelling exercise. The smallest global deviance value corresponded to the age-transformation power $\lambda=0.05$. The search for the best $\mathrm{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=4$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=4$. The model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=4\right.$, $\operatorname{df}(v)=4, \tau=2$ ) was selected to predict the girls' 3-month interval parameter curves up to age 12 months.

In accordance with step 3 of the methodology described in section 2.5 , those parameter estimates were joined to their equivalents obtained from the 2 - and 4 -month interval models (birth to 24 months) using the unified delta value ( 800 g ) and a cubic spline surface was fitted for each parameter ( $\mathrm{L}, \mathrm{M}$ and S). The resulting predicted parameter estimates for interval 3-months (birth to 24 months) were used to construct the final centiles for girls.

The diagnostic results are presented in Appendix A3, section A3.3b. The concordance between the predicted centiles and empirical values was evaluated by the comparisons in figures A3.24 to A3.26. Those show a slight over-estimation of about 50 g in the $75^{\text {th }}$ and $90^{\text {th }}$ centiles.

Table 9 presents the predicted centiles for girls' 3-month weight velocities between birth and 24 months.

### 3.1.4 4-month intervals

## Boys

There were 6058 4-month weight increments for boys, two of which were excluded as outliers, leaving a final sample of 6056 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=11$ and $\operatorname{df}(\sigma)=5$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\operatorname{df}(v)=6$ but with negligible difference from that yielded when $\operatorname{df}(v)=5$. The model with the smaller $\operatorname{df}(v)$ was selected, i.e. model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=11, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=5, \tau=2\right)$ and further evaluated.

The diagnostic results are presented in Appendix A3, section A3.4a. The Q-test results (Table A3.5) and worm plots (Figure A3.27) from this model indicated residual skewness in only 1 out of 15 age groups, with an overall Q-test p-value that was only marginally significant at the $5 \%$ level and thus the model was considered adequate. Figure A3.28 shows the fitted $\mu, \sigma$ and $v$ curves against their corresponding empirical estimates. Although there are notable fluctuations for the $\sigma$ and $v$ parameters, the fitted curves seem adequate. The next three plots (figures A3.29 to A3.31) show no evidence of bias when comparing fitted against empirical centiles or centile residuals, except for an underestimation in the $5^{\text {th }}$ and $10^{\text {th }}$ centiles, and an over-estimation in the $75^{\text {th }}$ centile both less than 50 g .

Table 10 presents the predicted centiles for boys' 4-month weight velocities between birth and 24 months.

## Girls

There were 6537 4-month weight increments for girls, four of which were excluded as outliers, leaving a final sample of 6533 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=9$ and $\operatorname{df}(\sigma)=5$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=5$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=5, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.4b. The Q-test results (Table A3.6) and worm plots (Figure A3.32) from this model indicated residual skewness in 3 out of 15 age groups. The overall Q-test p-value was marginally significant at the $5 \%$ level ( $p$-value $=0.0441$ ). Figure A3.33 shows adequate fitting of the parameters $\mu$, $\sigma$ and $\nu$ with the respective sample estimates. Comparisons between fitted and empirical centiles and centile residuals depict patterns of under-estimation in the $10^{\text {th }}$ and $97^{\text {th }}$ centiles and over-estimation in the $75^{\text {th }}$ centile by about 50 g (Figures A3.34 to A3.36). In sum, the selected model was considered adequate for constructing the 4-month velocity for girls.

Table 11 presents the predicted centiles for girls' 4-month weight velocities between birth and 24 months.

### 3.1.5 6-month intervals

## Boys

There were 5247 6-month weight increments for boys, one of which was excluded as an outlier, leaving a final sample of 5246 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=10$ and $\operatorname{df}(\sigma)=5$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\operatorname{df}(v)=3$. Thus the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=10, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=3, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.5a. The Q-test results (Table A3.7) and worm plots (Figure A3.37) from this model indicated residual skewness in only 1 out of 13 age groups, with an overall Q-test p-value that was non-significant at the $5 \%$ level and thus the model was considered adequate. Figure A3.38 shows the fitted $\mu, \sigma$ and $\nu$ curves against their corresponding empirical estimates. There are some fluctuations for the parameter $v$ yet the fitted curve seems adequate. The next three plots (figures A3.39, A3.40 and A3.41) show a slight bias (of about 50 g ) when comparing fitted against empirical centiles or centile residuals at the $5^{\text {th }}$ and $10^{\text {th }}$ centiles (underestimation) and at the $75^{\text {th }}$ and $90^{\text {th }}$ centiles (over-estimation).

Table 12 presents the predicted centiles for boys' 6-month weight velocities between birth and 24 months.

## Girls

There were 5662 6-month weight increments for girls, five of which were excluded as outliers, leaving a final sample of 5657 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=5$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\operatorname{df}(v)=4$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=7, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=4, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A3, section A3.5b. The Q-test results (Table A3.8) and worm plots (Figure A3.42) from this model indicated residual skewness in 2 out of 13 age groups. The overall $Q$-test $p$-value for this parameter was marginally significant at the $5 \%$ level (p-value $=0.0448$ ). Figure A3.43 shows adequate fitting of the parameters $\mu, \sigma$ and $\nu$ with the respective sample estimates. Comparisons between fitted and empirical centiles and centile residuals depict patterns of under-estimation in the $5^{\text {th }}$ and $10^{\text {th }}$ centiles by less than 50 g and over-estimation in the $75^{\text {th }}$ and $90^{\text {th }}$ centiles by about 50 g (Figures A3.44 to A3.46). In sum, the selected model was considered adequate for constructing the 6-month velocity for girls.

Table 13 presents the predicted centiles for girls' 6-month weight velocities between birth and 24 months.

a The L, M, S values provided are estimated based on the modelling of the shifted observations (i.e. by the addition of delta to the actual increment) which explains the
difference (equals to delta) in value between the " M " and the $50^{\text {th }}$ centile (or Median) values.

Table 5 Girls 1-month weight increments (g)

### 3.2 Centile tables of weight velocity by birth weight category from birth to 60 days

This section provides sex-specific centiles for weight increments conditional on birth weight for oneor two-week intervals from birth to 2 months following the MGRS longitudinal component visits schedule. The values are presented both as net increments in grams and as $\mathrm{g} /$ day over each index period. The tables, which present the median and the $25^{\text {th }}, 10^{\text {th }}$ and $5^{\text {th }}$ centiles that were generated based on empirical estimates, are expected to be particularly useful for lactation management purposes.

The estimation of the centiles was done using the STATA software, which applies a simple method of ranking observations in the sample. The rows of the tables show age intervals in days and the columns provide the grouping of the birth weights in grams. Only the median is provided when the sample size is too small, as happened for the birth-weight group 2 to 2.5 kg . Tables 14 and 16 show the weight gain values by birth-weight group and age interval for boys and girls, respectively. Tables 15 and 17 present the sex-specific daily weight gain values by birth-weight groups and age interval. The daily weight gains, $\mathrm{g} / \mathrm{d}$, are not the simple average of the gross gains or losses reported in corresponding weekly and fortnightly tables. Instead, these figures come from calculating individual daily increments for newborns in each of the birth-weight categories and then estimating centiles directly from the raw $\mathrm{g} / \mathrm{d}$ values.

Table 14 Boys weight increments (g) by birth-weight groups

| $\begin{gathered} \text { Age } \\ \text { (days) } \end{gathered}$ |  | Birth weight (g) |  |  |  |  |  |

## 4. CONSTRUCTION OF THE LENGTH VELOCITY STANDARDS

The objective was to create sex-specific velocity curves for 2 -, 3 -, 4 - and 6 -month length increments conditional on age. Tables generated from the 2-month increment curves provide estimated centiles for ages $0-2,1-3, \ldots, 22-24$ months; tables generated from the 3 -month increment curves provide estimated centiles for ages $0-3,1-4, \ldots, 21-24$ months; tables generated from the 4 -month increment curves provide estimated centiles for ages $0-4,1-5, \ldots, 20-24$ months; and tables generated from the 6 -month increment curves provide estimated centiles for ages $0-6,1-7, \ldots, 18-24$ months.

Negative length increments are clearly the result of measurement error since children cannot grow shorter. On the strength of biology, therefore, negative increments were recoded as "no growth" by assigning the nominal value of +0.01 to enable their inclusion in the BCPE modelling. The numbers involved were small: for the 2-month increments for boys 11 out of 7016 ( $0.16 \%$ ) between -0.5 and -0.05 cm , and for girls 15 out of $7504(0.20 \%)$ between -0.75 and -0.05 cm . To examine if the recoding of these few negative values had an impact on the final centiles, one comparison was made using the girls' 2 -month length increments with the negative (adding a delta value to all observations) versus the recoded values. This group was selected since it had a larger number of negative increments. The recoding had no impact on the model specifications and the resulting centiles changed only slightly, by at most 0.1 cm , and for very few cases. At the -3SD, the two models yielded identical estimates for the intervals between birth and 14 months. For the later ages, the analysis including the negative increments resulted in negative centile estimates ranging between -0.1 cm (14-16 months) and -0.5 cm (22-24 months). Treating negative increments as zero growth constrained centile estimates to be zero or above but did not introduce bias. Using the nominal shift to "no growth" thus averted the biological contradiction of expected/predicted negative growth at the extreme low centiles.

### 4.1 2-month intervals

## Boys

There were 7016 2-month length increments for boys, one of which was excluded as an outlier, leaving a final sample of 7015 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=9$ and $\operatorname{df}(\sigma)=7$ provided the smallest GAIC( 3 ). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=1$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=7, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A4, section A4.1a. The overall Q-test p-values (Table A4.1) indicate an adequate fit of the parameters $\mu$ and $\sigma$ ( p -values $>0.05$ ) yet a significant $p$-value for the skewness parameter $v$. This was caused by residual skewness (absolute z 3 values larger than 2) in three out of 17 age groups. The worm plots (Figure A4.1) from this model agree with the Q-test results. By contrast, the fitted curves of the parameters $\mu, \sigma$ and $v$ seemed adequate when compared to the empirical values (Figure A4.2). The fitted centile curves and empirical centiles, which are shown in figures A4.3 and A4.4, indicate close concordance between the two. Figure A4.5 shows the distribution of empirical minus fitted centile differences with no indication of systematic bias except for a slight under-estimation of the $25^{\text {th }}$ centile by about 0.05 cm .

Table 18 presents the predicted centiles for boys' 2-month length velocities between birth and 24 months.

## Girls

There were 7504 2-month length increments for girls. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=10$ and $\operatorname{df}(\sigma)=7$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=1$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=10, \operatorname{df}(\sigma)=7, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A4, section A4.1b. The Q-test results (Table A4.2) and worm plots (Figure A4.6) indicated an adequate fit of the parameters $\mu$ and $\sigma$. There were four out of 17 groups with residual skewness, resulting in a significant $p$-value for the overall test of the $v$ parameter at level $5 \%$. Furthermore, figure A4.7 displays adequate fitting of the parameters $\mu$ and $\sigma$, and reasonable smoothing of the fluctuations in the $v$ parameter when compared with the respective sample estimates. Similar to the boys, comparisons between fitted and empirical centiles and centile residuals depict some patterns of negligible biases usually less than 0.1 cm (Figures A 4.8 to A4.10).

Table 19 presents the predicted centiles for girls' 2-month length velocities between birth and 24 months.

### 4.2 3-month intervals

## Boys

There were 4545 3-month length increments for boys, two of which were excluded as outliers, leaving a final sample of 4543 observations for the modelling exercise. The best value of the agetransformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=6$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC(3) value corresponded to $\operatorname{df}(v)=1$ and thus the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=7, \operatorname{df}(\sigma)=6, \operatorname{df}(v)=1, \tau=2\right)$ was selected to predict the boys' 3-month interval parameter curves up to age 12 months (see step 2 in section 2.5).

Those parameter estimates were joined to their equivalents obtained from the 2-and 4-month interval models (birth to 24 months) and a cubic spline surface was fitted for the $\mu$ and $\sigma$ parameters ( M and S ). For the L curve, the fitted constant $(\operatorname{df}(v)=1$ in the model above for the first year) was projected into the second year. The resulting predicted parameter estimates for the 3-month interval (birth to 24 months) from the fitted spline surface ( M and S ) plus the constant value for $L$ were used to construct the final centiles for the boys' 3-month interval.

The diagnostic test results are presented in Appendix A4, section A4.2a. Figures A4.11 to A4.13 show negligible size bias (of about 0.1 cm over-estimation) comparing the empirical and fitted centiles, and the centile residuals, in the $75^{\text {th }}$ centile and above.

Table 20 presents the predicted centiles for boys' 3-month length velocities between birth and 24 months.

## Girls

There were 4866 3-month length increments for girls, one of which was excluded as an outlier, leaving a final sample of 4865 observations for the modelling exercise. The smallest global deviance value corresponded to the age-transformation power $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=5$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=1$. The model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=5\right.$, $\operatorname{df}(v)=1, \tau=2)$ was selected to predict the girls' 3-month interval parameter curves up to age 12 months.

Following step 3 of the methodology described in section 2.5, those parameter estimates were joined to their equivalents obtained from the 2 - and 4 -month interval models (birth to 24 months) for the $\mu$ and $\sigma$ parameters ( M and S ) and a cubic spline surface was used to fit each of these parameters. Similar to boys, the fitted constant for the $v$ parameter $(\mathrm{L})$ was projected from the first into the second year. The predicted parameter estimates from the fitted spline surface ( M and S ) for 3-month interval (birth to 24 months) plus the constant value for $L$ were used to construct the final centiles for the girls' 3-month interval.

The diagnostic test results are presented in Appendix A4, section A4.2b. Comparisons between fitted and empirical centiles (A4.14 and A4.15) and centile residuals (A4.16) show only an average overestimation smaller than 0.1 cm in the $75^{\text {th }}$ centile.

Table 21 presents the predicted centiles for girls' 3-month weight velocities between birth and 24 months.

### 4.3 4-month intervals

Boys
There were 6183 4-month length increments for boys. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=5$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest GAIC( 3 ) value corresponded to $\operatorname{df}(v)=1$, and the model $\operatorname{BCPE}\left(x=\right.$ age $\left.^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic test results are presented in Appendix A4, section A4.3a. The Q-test results (Table A4.3) and worm plots (Figure A4.17) from this model indicated an adequate fit of the data with only 1 out of 15 age groups showing misfit of the median (absolute $z 1>2$ ) and 2 out of 15 age groups with residual skewness (absolute $z 3>2$ ). Yet the overall Q-test p-value was non-significant at the $5 \%$ level and thus the model was considered adequate. Figure A4.18 shows the fitted $\mu, \sigma$ and $v$ curves against their corresponding empirical estimates. The $v$ parameter empirical curve exhibits fluctuations that are reasonably averaged by the fitted value. The next three plots (figures A4.19, A4.20 and A4.21) show no evidence of bias when comparing fitted to empirical centiles or centile residuals, except for a slight under-estimation in the $10^{\text {th }}$ and lower centiles by about 0.1 cm .

Table 22 presents the predicted centiles for boys' 4-month length velocities between birth and 24 months.

## Girls

There were 66204 -month length increments for girls. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=5$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=1$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A4, section A4.3b. The Q-test results (Table A4.4) and worm plots (Figure A4.22) from this model indicated clearly that it was adequate for constructing the 4 -month velocity curves for girls. Figure A4.23 shows adequate fitting of the parameters $\mu$ and $\sigma$ with the respective sample estimates and a fair constant fitting of the fluctuations in the empirical curve for $v$ by the selected model. Comparisons between fitted and empirical centiles and centile residuals depict a reasonable fit of the data with a slight over-estimation in the $75^{\text {th }}$ centile by about 0.05 cm (Figures A4.24 to A4.26).

Table 23 presents the predicted centiles for girls' 4-month length velocities between birth and 24 months.

### 4.4 6-month intervals

## Boys

There were a total of 5358 6-month length increments for boys, one of which was excluded as an outlier, leaving a final sample of 5357 increments for the modelling exercise. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05$, $v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=5$ corresponded to the smallest GAIC( 3 ). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. Although the smallest GAIC(3) value corresponded to $\operatorname{df}(v)=3$, the model with $\operatorname{df}(v)=1$ was also considered to be more consistent with the other intervals. Since there were no detectable differences in the final centiles estimated by either model, the simpler model (i.e. $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=7, \operatorname{df}(\sigma)=5, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic test results are presented in the Appendix A4, section A4.4a. The Q-test results (Table A4.5) and worm plots (Figure A4.27) from this model indicated an adequate fit of the data with only 1 out of 13 age groups showing misfit of the skewness (absolute $\mathrm{z} 3>2$ ). Yet the overall Q -test p -value was non-significant at the $5 \%$ level and thus the model was considered adequate. Figure A4.28 shows the fitted $\mu, \sigma$ and $v$ curves against their corresponding empirical estimates. The $v$ parameter empirical curve fluctuated and was well averaged by the fitted constant value. The next three plots (figures A4.29, A4.30 and A4.31) show no evidence of bias when comparing fitted to empirical centiles or centile residuals, except for a slight over-estimation by about 0.1 cm in the $90^{\text {th }}$ and $95^{\text {th }}$ centiles.

Table 24 presents the predicted centiles for boys' 6-month length velocities between birth and 24 months.

## Girls

There were 5739 6-month length increments for girls. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=4$ provided the smallest $\operatorname{GAIC}(3)$. The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=1$ and the model $\operatorname{BCPE}\left(x=\right.$ age $\left.^{0.05}, \operatorname{df}(\mu)=7, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=1, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A4, section A4.4b. The Q-test results (Table A4.6) and worm plots (Figure A4.32) from this model indicated clearly that it was adequate for constructing the 6 -month velocity curves for girls. Figure A4.33 shows adequate fitting of the parameters $\mu$ and $\sigma$ curves with the respective sample estimates. The fluctuations in the empirical curve for $v$ are fitted reasonably well by the constant in the selected model. Comparisons between fitted and empirical centiles and centile residuals depict fair concordance between the empirical and fitted data (Figures A4.34 to A4.36).

Table 25 presents the predicted centiles for girls' 6-month length velocities between birth and 24 months.

Table 18 Boys 2-month length increments (cm)

| Interval | L | M | S | 1st | 3rd | 5th | 15th | 25th | 50th | 75th | 85th | 95th | 97th | 99th |

## Appendix A4 Diagnostics

A4.1a 2-month intervals for boys
Table A4.1 Q-test for $z$-scores from selected model $\left[B C P E\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=7, \operatorname{df}(v)=1\right.\right.$, $\tau=2$ )] for 2-month length velocity for boys

| Age (days) | Group | N | z1 | z2 | z3 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 55 to 76 | 0-2 mo | 422 | -0.4 | 0.6 | -1.9 |
| 76 to 107 | $1-3 \mathrm{mo}$ | 417 | 1.5 | -1.3 | 2.1 |
| 107 to 137 | 2-4 mo | 416 | -0.9 | 0.3 | 1.1 |
| 137 to 168 | $3-5 \mathrm{mo}$ | 413 | 0.7 | -0.1 | 1.6 |
| 168 to 198 | 4-6 mo | 416 | -0.8 | 0.3 | 0.5 |
| 198 to 229 | 5-7 mo | 412 | -0.6 | 0.9 | 0.3 |
| 229 to 259 | 6-8 mo | 417 | -0.4 | -0.5 | -1.1 |
| 259 to 289 | $7-9 \mathrm{mo}$ | 409 | 0.0 | 1.1 | 0.4 |
| 289 to 320 | 8-10 mo | 404 | 0.8 | -0.7 | -1.9 |
| 320 to 350 | $9-11 \mathrm{mo}$ | 411 | 0.4 | 0.8 | -0.1 |
| 350 to 396 | 10-12 mo | 405 | -0.6 | -1.8 | -0.6 |
| 396 to 457 | 12-14 mo | 415 | 0.6 | 1.0 | 0.4 |
| 457 to 518 | 14-16 mo | 410 | -1.0 | 0.7 | -1.0 |
| 518 to 579 | 16-18 mo | 407 | 0.8 | -1.0 | -2.7 |
| 579 to 640 | 18-20 mo | 412 | -0.9 | 0.9 | 1.0 |
| 640 to 701 | 20-22 mo | 415 | 0.9 | 0.0 | -1.0 |
| 701 to 738 | 22-24 mo | 414 | -0.8 | 1.2 | -2.0 |
| Overall Q stats |  | 7015 | 10.0 | 13.3 | 31.8 |
| degrees of freedom |  |  | 8.0 | 13.0 | 16.0 |
| p-value |  |  | 0.2625 | 0.4241 | 0.0105 |

Note: Absolute values of $\mathrm{z} 1, \mathrm{z} 2$ or z3 larger than 2 indicate misfit of, respectively, mean, variance or skewness.

Unit normal quantile
Figure A4.1 Worm plots from selected model [BCPE $\left.\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=7, \operatorname{df}(v)=1, \tau=2\right)\right]$ for 2-month length velocity for boys

Figure A4.2 Fitting of the $\mu, \sigma$, and $v$ curves of selected model for 2-month length velocity for boys

Figure A4.3 3rd, 10th, 50th, 90th, 97th smoothed centile curves and empirical values: 2-month length velocity for boys

Figure A4.4 5th, 25th, 50th, 75th, 95th smoothed centile curves and empirical values: 2-month length velocity for boys

Figure A4.5 Centile residuals from fitting selected model for 2-month length velocity for boys

## A4.1b 2-month intervals for girls

Table A4.2 Q-test for $z$-scores from selected model $\left[B C P E\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=10, \operatorname{df}(\sigma)=7, \operatorname{df}(v)=1\right.\right.$, $\tau=2$ )] for 2-month length velocity for girls

| Age (days) | Group | N | z1 | z2 | z3 |
| :--- | :---: | :---: | ---: | ---: | ---: |
| 58 to 76 | $\mathbf{0 - 2} \mathbf{~ m o}$ | 446 | 0.1 | 0.5 | 0.9 |

## 5. CONSTRUCTION OF THE HEAD CIRCUMFERENCE VELOCITY STANDARDS

The objective was to create sex-specific velocity curves for 2 -, 3 -, 4 - and 6 -month head circumference increments conditional on age. Tables generated from the 2-month increment curves provide estimated centiles for ages $0-2,1-3, \ldots, 10-12$ months; tables generated from the 3 -month increment curves provide estimated centiles for ages $0-3,1-4, \ldots, 9-12$ months; tables generated from the 4 -month increment curves provide estimated centiles for ages $0-4,1-5, \ldots, 20-24$ months; and tables generated from the 6 -month increment curves provide estimated centiles for ages $0-6,1-7, \ldots, 18-24$ months. To avoid the right-edge effect, the 2- and 3-month intervals were modelled using data up to age 14 months.

By the same rationale applied to length increments, negative increments were recoded as "no growth" by assigning the nominal value of +0.01 to permit their inclusion in BCPE modelling. The numbers involved were: for the 2 -month increments for boys 15 out of $4947(0.30 \%)$ between -0.85 and -0.05 cm , and for girls 26 out of $5316(0.49 \%$ ) between -0.70 and -0.02 cm ; for the 3-month increments for boys 4 out of $4536(0.09 \%)$ between -0.30 and -0.05 cm and for girls 5 out of 4869 $(0.10 \%)$ between -0.55 and -0.001 cm ; for the 4 -month increments for boys 19 out of $6178(0.31 \%)$ between -0.30 and -0.008 cm , and for girls 24 out of $6629(0.36 \%)$ between -0.45 and -0.05 cm ; for the 6 -month increments for boys 2 out of $5353(0.04 \%)$ between -0.15 and -0.04 cm , and for girls 6 out of $5747(0.10 \%)$ between -0.30 and -0.05 cm . As was the case for length, the effect of recoding the negative values on the final centiles was assessed using the girls' 2 -month head circumference increments (the group with the largest number of negative increments). Comparisons between the model using the negative values (adding a delta value to all observations) and the model using recoded values showed that the recoding had no impact on the model specifications and results were comparable to those of length.

### 5.1 2-month intervals

## Boys

There were 4947 2-month boys' head circumference increments from birth to 14 months. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. Neither criterion GAIC(3) nor GAIC(4) was able to select the best degrees of freedom for the parameter $\mu$. It was only with $\operatorname{GAIC}(5)$ that the search results indicated minima values. The model yielding the first smallest GAIC(5) was selected in favour of a smoother median curve. Thus, $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=4$ were used to continue with a search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$. The smallest GAIC(5) value corresponded to $\operatorname{df}(v)=1$ yet the $v$ curve using this was an under-smoothed fit of the empirical Box-Cox power values. Thus a choice was made to use $\operatorname{df}(v)=4$, which was primarily supported by criteria $\operatorname{GAIC}(3)$ and $\operatorname{GAIC}(4)$, and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=4, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A5, section A5.1a. The overall Q-test p-values (Table A5.1) indicate an adequate fit of the parameters $\mu$ and $\sigma(p$-values $>0.05)$ with residual skewness (absolute z3 values > 2 ) in only one out of 12 age groups ( $7-9 \mathrm{mo}$ ). The worm plots (Figure A5.1) from this model agree with the Q-test results. The fitted curves of the parameters $\mu, \sigma$ and $v$ seemed adequate when compared to the empirical values (Figure A5.2). The fitted centile curves and empirical centiles are shown in figures A5.3 and A5.4, and they indicate close concordance between the two. Figure A5.5 shows the distribution of empirical minus fitted centile differences with no evidence of systematic bias except for a slight over-estimation of the $75^{\text {th }}, 90^{\text {th }}$ and $95^{\text {th }}$ centiles by about 0.05 cm .

Table 26 presents the predicted centiles for boys' 2-month head circumference velocities between birth and 12 months.

## Girls

There were 5316 girls' 2-month head circumference increments from birth to 14 months. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The GAIC(3) reached more than one local minima, the first occurring for the model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=4$. The next minimum for the GAIC(3) was yielded by a model of considerably higher degrees of freedom and lesser smoothness $(\operatorname{df}(\mu)=11$ and $\operatorname{df}(\sigma)=4)$. In favour of greater smoothness, the model with $\operatorname{df}(\mu)=8$ and $\operatorname{df}(\sigma)=4$ was further examined and the next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\mathrm{df}(v)=1$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}{ }^{0.05}, \operatorname{df}(\mu)=8, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=1\right.$, $\tau=2$ ) was further evaluated.

The diagnostic test results are presented in Appendix A5, section A5.1b. For the selected model, the Q-test results (Table A5.2) show overall Q-test for $\mu$ and $\sigma$ with p-values above 0.05 indicating an adequate fit of these parameters. For the parameter $v$, the overall Q-test was significant indicating residual skewness (absolute z 3 values $>2$ ) in two out of 12 age groups. The worm plots (Figure A5.6) show similar results to those of the Q-test. Figure A5.7 displays the fitted curves of the parameters $\mu$ and $\sigma$, which closely followed the respective empirical point estimates; the model fitting a constant for the parameter $v$ also approximates fairly well the fluctuations observed empirically. Similar to the boys, comparisons between fitted and empirical centiles are in close agreement, and centile residuals depict slight over-estimation by about 0.05 cm of the $75^{\text {th }}$ and higher centiles (Figures A5.8 to A5.10).

Table 27 presents the predicted centiles for girls' 2-month head circumference velocities between birth and 12 months.

### 5.2 3-month intervals

## Boys

There were 4536 boys' 3-month observed head circumference increments from birth to 14 months. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. Once more, the GAIC(3) reached more than one local minima values, the first occurring for the model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=4$. The next minimum for the GAIC(3) came from a model of considerably higher degrees of freedom and lesser smoothness $(\operatorname{df}(\mu)=13$ and $\mathrm{df}(\sigma)=4)$. To maintain the smoother fit (with the lower degrees of freedom for $\mu$ ), the model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=4$ was selected, followed by the search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=4$ and the model $\operatorname{BCPE}\left(x=\right.$ age $\left.^{0.05}, \operatorname{df}(\mu)=7, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=4, \tau=2\right)$ was further evaluated.

The diagnostic results are presented in Appendix A5, section A5.2a. In Table A5.3, the overall Q-test p -values for the median, variance and skewness were all non-significant, indicating an adequate fit of the boys' 3-month head circumference increments. Similarly, the worm plots shown in Figure A5.11 of the selected model indicate an adequate fit of the data. There was no evident bias when comparing fitted $\mu, \sigma$ and $v$ parameter curves with their respective sample estimates (Figure A5.12). Figures A5.13 to A5.15 show no sizeable bias comparing the empirical and fitted centiles, and the centile residuals.

Table 28 presents the predicted centiles for boys' 3-month head circumference velocities between birth and 12 months.

## Girls

There were 4869 girls' 3-month observed head circumference increments from birth to 14 months. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. Using $\operatorname{GAIC}(3)$ there was no minimum value and that was also the case when the penalty was raised to 4 . With penalty 5 (GAIC(5)) the first occurring minimum value was associated with the model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=4$. Next, the GAIC(5) indicated a smaller value only with considerably higher degrees of freedom and lesser smoothness $(\operatorname{df}(\mu)=15$ or higher and $\operatorname{df}(\sigma)=4)$. Thus, the model with $\operatorname{df}(\mu)=7$ and $\operatorname{df}(\sigma)=4$ was used to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=4$, while the smallest $\operatorname{GAIC}(5)$ indicated $\operatorname{df}(v)=2$. The choice that provided the smoother $v$ curve, i.e. $\operatorname{df}(v)=2$, was selected and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=7, \operatorname{df}(\sigma)=4, \operatorname{df}(v)=2, \tau=2\right)$ was further evaluated.

The diagnostic test results are presented in Appendix A5, section A5.2b. In Table A5.4, the overall Qtest for the median parameter $\mu$ was significant, but none of the $z 1$ values exceed absolute value 2 , and the same applied to the skewness parameter $v$ ( 2 out of $11 \mathrm{z3}$ values exceed absolute value 2 ). The overall significance, especially for the median might be due in part to the small number of age groups (11) for this interval relative to the number of degrees of freedom necessary for fitting the parameter, which leaves a small number of degrees of freedom for the overall Q-test statistics. The worm plots (Figure A5.16) confirm findings of the Q-tests (i.e. one group with a U-shaped worm and another with an inverted U-shaped worm). Examining figure A5.17 of the fitted parameters, there were fluctuations notably in the empirical curve of the parameter $v$ that were smoothed out by the selected model. The adequacy of the fitted model was indicated by the comparisons between fitted and empirical centiles (A5.18 and A5.19) and centile residuals (A5.20), the latter showing an average under-estimation of 0.05 cm in the $10^{\text {th }}$ centile and an equally negligible over-estimation in the $90^{\text {th }}$ centile.

Table 29 presents the predicted centiles for girls' 3-month head circumference velocities between birth and 12 months.

### 5.3 4-month intervals

Boys

There were 6178 boys' 4-month head circumference increments from birth to 24 months, one of which was excluded as an outlier, leaving a final sample of 6177 observations for the modeling exercise. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=10$ and $\operatorname{df}(\sigma)=5$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=3$. Hence, the model $\operatorname{BCPE}\left(x=a g e^{0.05}, \operatorname{df}(\mu)=10\right.$, $\operatorname{df}(\sigma)=5, \operatorname{df}(v)=3, \tau=2)$ was selected and further evaluated.

The diagnostic test results are presented in Appendix A5, section A5.3a. The Q-test results (Table A5.5) and worm plots (Figure A5.21) from this model indicated an adequate fit of the data with the overall Q-test p-values for the three parameters being non-significant at the $5 \%$ level. Figure A5.22 shows the fitted $\mu, \sigma$ and $\nu$ curves against their corresponding empirical estimates. Notably, the $v$ parameter empirical curve exhibits fluctuations which are reasonably smoothed by the fitted curve. The next three plots (figures A5.23, A5.24 and A5.25) show no evidence of bias when comparing fitted against empirical centiles or centile residuals, except for a slight over-estimation in the $75^{\text {th }}, 90^{\text {th }}$ and $95^{\text {th }}$ centiles by about 0.05 cm .

Table 30 presents the predicted centiles for boys' 4-month head circumference velocities between birth and 24 months.

## Girls

There were 6629 girls' 4-month head circumference increments from birth to 24 months, one of which was excluded as an outlier, leaving a final sample of 6628 observations for the modeling exercise. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, \nu=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=10$ and $\operatorname{df}(\sigma)=5$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=2$ and the model $\operatorname{BCPE}\left(x=a g e^{0.05}, \operatorname{df}(\mu)=10\right.$, $\operatorname{df}(\sigma)=5, \operatorname{df}(v)=2, \tau=2)$ was further evaluated.

The diagnostic test results are presented in Appendix A5, section A5.3b. The overall Q-test p-values (in Table A5.6) indicate an adequate fit of the median parameter $\mu$ and $\sigma$ curves. For the skewness parameter $v$ although the overall Q-test was significant, residual skewness occurred in only two out of 15 age groups. The worm plots (Figure A5.26) from this model reflect residual skewness in the same age group as indicated by the Q-test results. Figure A5.27 shows adequate fitting of the parameters $\mu$ and $\sigma$ with the respective sample estimates and a reasonable smoothing of the fluctuations in the empirical curve for $v$ by the selected model. Comparisons between fitted and empirical centiles and centile residuals depict a reasonable fit of the data (Figures A5.28 and A5.29) with a slight underestimation in the $10^{\text {th }}$ centile by about 0.05 cm and a similar over-estimation in the $75^{\text {th }}$ and higher centiles (Figure A5.30).

Table 31 presents the predicted centiles for girls' 4-month head circumference velocities between birth and 24 months.

### 5.4 6-month intervals

## Boys

There were 5353 boys' 6-month head circumference increments from birth to 24 months, one of which was excluded as an outlier, leaving a final sample of 5352 observations for the modelling exercise. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\mathrm{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=9$ and $\operatorname{df}(\sigma)=4$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=2$. Hence, the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9\right.$, $\operatorname{df}(\sigma)=4, \operatorname{df}(v)=2, \tau=2)$ was selected and further evaluated.

The diagnostic test results are presented in Appendix A5, section A5.4a. The Q-test results (Table A5.7) and worm plots (Figure A5.31) from this model indicated an adequate fit of the data with the overall Q-test p-values for the three parameters being non-significant at the $5 \%$ level. Figure A5.32 shows the fitted $\mu, \sigma$ and $\nu$ curves against their corresponding empirical estimates. The $v$ parameter fitted curve smoothes out reasonably well the fluctuations exhibited by the empirical curve. Figures A5.33, A5.34 and A5.35 show some evidence of bias in the comparison of fitted against empirical centiles and centile residual plots at the lowest centiles (between the $3^{\text {rd }}$ and the $10^{\text {th }}$ centiles) but the magnitude of the biases is negligible.

Table 32 presents the predicted centiles for boys' 6-month head circumference velocities between birth and 24 months.

## Girls

There were 5747 girls' 6-month head circumference increments from birth to 24 months, one of which was excluded as an outlier, leaving a final sample of 5746 observations for the modelling exercise. The best value of the age-transformation power was $\lambda=0.05$. The search for the best $\operatorname{df}(\mu)$ and $\operatorname{df}(\sigma)$ followed, fixing $\lambda=0.05, v=1$ and $\tau=2$. The model with $\operatorname{df}(\mu)=9$ and $\operatorname{df}(\sigma)=5$ provided the smallest GAIC(3). The next step was to search for the best degrees of freedom to fit the parameter $v$ for skewness fixing $\tau=2$ and keeping the degrees of freedom for the previously selected $\mu$ and $\sigma$ curves. The smallest $\operatorname{GAIC}(3)$ value corresponded to $\operatorname{df}(v)=2$ and the model $\operatorname{BCPE}\left(x=\operatorname{age}^{0.05}, \operatorname{df}(\mu)=9, \operatorname{df}(\sigma)=5\right.$, $\operatorname{df}(v)=2, \tau=2)$ was further evaluated.

The diagnostic test results are presented in Appendix A5, section A5.4b. Table A5.8 summarizes Q-test results, indicating an adequate fit of the median and skewness parameters and a slight misfit of the $\sigma$ parameter curve in the last two age groups (out of 13 ). The overall Q -test p -values were all nonsignificant. The worm plots (Figure A5.36) from this model partially reflect the variance misfit in one age group (18-24 mo). Figure A5.37 shows adequate fitting of the three parameters $\mu$, $\sigma$ and $\nu$ by the selected model. Comparisons between fitted and empirical centiles and the centile residuals depict a reasonable fit of the data (Figures A5.38 to A5.40). Similar to boys, there is a slight indication of bias but the magnitude also is negligible.

Table 33 presents the predicted centiles for girls' 6-month head circumference velocities between birth and 24 months.

## 6. COMPUTATION OF CENTILES AND Z-SCORES FOR VELOCITIES BASED ON WEIGHT, LENGTH AND HEAD CIRCUMFERENCE

The same method used to calculate centiles and z-scores for the attained growth standards based on weight is used to calculate centiles and $z$-scores for the velocity standards based on weight, length and head circumference increments. Briefly, the computation of percentiles and z-scores for these standards uses formulae based on a restricted application of the LMS method as used for the attained growth weight-based indicators, limiting the Box-Cox normal distribution to the interval corresponding to $z$-scores where empirical data were available (i.e. between -3 SD and +3 SD ). Beyond these limits, the standard deviation at each age was fixed to the distance between $\pm 2 \mathrm{SD}$ and $\pm 3 \mathrm{SD}$, respectively. This approach avoids making assumptions about the distribution of data beyond the limits of the observed values (WHO Multicentre Growth Reference Study Group, 2006a).

Adjustment to the basic methodology had to be applied for weight velocities conditional on age (see section 2.5). Children experience weight losses and, consequently, weight increments occur in negative values while the BCPE distribution can handle only positive values. Thus, before the BCPE could be applied to these data, it was necessary to add a constant value $\delta$ (delta) to all increments to shift their distribution above zero and, subsequently, to subtract delta from the predicted centiles. To calculate individual z scores, $\delta$ is first added to the child's increment and then the L, M and S values of the model are fitted on the shifted observations. When a child's increment is less than $-\delta$ (i.e. the increment is negative and its absolute value is greater than $\delta$ ), the correction applied for skewed attained growth standards beyond -3 SD or +3 SD will be used, since in reality such an increment lies below -3 SD.

For all indicators, the tabulated fitted values of Box-Cox power, median and coefficient of variation corresponding to the visit age $t$ are denoted by $L(t), M(t)$ and $S(t)$, respectively.

## Centiles and z-scores for weight velocities conditional on age

Note that in this case, the values of $L(t), M(t)$ and $S(t)$ are based on the shifted BCPE distribution. Given the value of $\delta$ for the corresponding standard, the centiles were calculated as follows:

$$
C_{100 \alpha}(t)=M(t)\left[1+L(t) S(t) Z_{\alpha}\right]^{1 / L(t)}-\delta, \quad-3 \leq Z_{\alpha} \leq 3
$$

The following procedure is recommended to calculate a $z$-score for an individual child with weight increment $y$ at the visit age $t$ :

1. Calculate

$$
z_{\text {ind }}=\frac{[(y+\delta) / M(t)]^{L(t)}-1}{S(t) L(t)}
$$

2. Compute the final z -score $\left(z_{\text {ind }}^{*}\right)$ of the child for that indicator as:

$$
z_{\text {ind }}^{*}=\left\{\begin{array}{ccc}
z_{\text {ind }} & \text { if } & \left|z_{\text {ind }}\right| \leq 3 \\
3+\left(\frac{(y+\delta)-S D 3 p o s}{S D 23 p o s}\right) & \text { if } & z_{\text {ind }}>3 \\
-3+\left(\frac{(y+\delta)-S D 3 n e g}{S D 23 n e g}\right) & \text { if } & z_{\text {ind }}<-3
\end{array}\right.
$$

where
SD3pos is the cut-off +3 SD calculated at $t$ by the LMS method:

$$
S D 3 \text { pos }=M(t)[1+L(t) * S(t) *(3)]^{1 / L(t)}
$$

SD3neg is the cut-off -3 SD calculated at $t$ by the LMS method:

$$
\text { SD3neg }=M(t)[1+L(t) * S(t) *(-3)]^{1 / L(t)} ;
$$

$S D 23$ pos is the difference between the cut-offs +3 SD and +2 SD calculated at $t$ by the LMS method:

$$
S D 23 \text { pos }=M(t)[1+L(t) * S(t) *(3)]^{1 / L(t)}-M(t)[1+L(t) * S(t) *(2)]^{1 / L(t)}
$$

and SD23neg is the difference between the cut-offs -2 SD and -3 SD calculated at $t$ by the LMS method:

$$
S D 23 n e g=M(t)[1+L(t) * S(t) *(-2)]^{1 / L(t)}-M(t)[1+L(t) * S(t) *(-3)]^{1 / L(t)}
$$

To illustrate the procedure, examples with the 2-month interval weight velocity conditional on age for boys follow.

Child 1: 6-month-old boy with an increment, i.e. weight gain 2200 g between 4 and 6 months.
$\mathrm{L}=0.5891 ; \quad \mathrm{M}=1541.3670 ; \quad \mathrm{S}=0.20130 ; \quad \delta=600$;
$\boldsymbol{z}_{\text {ind }}=\frac{[(2200+600) / 1541.3670]^{0.5891}-1}{0.20130 * 0.5891}=3.55 \quad>3$

```
\(\boldsymbol{S D} 3\) pos \(=1541.3670 *[1+(0.5891) * 0.20130 *(3)]^{1 /(0.5891)}=2583.96\)
\(\boldsymbol{S D} 2\) pos \(=1541.3670 *[1+(0.5891) * 0.20130 *(2)]^{1 /(0.5891)}=2212.11\)
\(\boldsymbol{S D} 23\) pos \(=2583.96-2212.11=371.85\)
```

$\Rightarrow z_{\text {ind }}^{*}=3+\left(\frac{(2200+600)-2583.96}{371.85}\right)=3.58$
Child 2: 18 -month-old boy with an increment of -500 g (weight loss of 500 g ) between 16 and 18 months.
$\mathrm{L}=0.8078 ; \quad \mathrm{M}=1000.9680 ; \quad \mathrm{S}=0.31615 ; \quad \delta=600 ;$

$$
z_{\text {ind }}=\frac{[(-500+600) / 1000.9680]^{0.8078}-1}{0.31615 * 0.8078}=-3.31<-3
$$

$$
\begin{aligned}
& \boldsymbol{S D} 2 \text { neg }=1000.9680 *[1+0.8078 * 0.31615 *(-2)]^{1 / 8.8078}=413.10 \\
& \boldsymbol{S D} 3 \text { neg }=1000.9680 *[1+0.8078 * 0.31615 *(-3)]^{1 / 8.8078}=165.65 \\
& \text { SD23neg }=413.10-165.65=247.45
\end{aligned}
$$

$$
\Rightarrow \quad z_{\text {ind }}^{*}=-3+\left(\frac{(-500+600)-165.65}{247.45}\right)=-3.27
$$

Child 3: 13-month-old boy with a weight gain of 1200 g between 11 and 13 months.
$\mathrm{L}=0.7191 ; \quad \mathrm{M}=1057.9071 ; \quad \mathrm{S}=0.28462 ; \quad \delta=600 ;$

$$
z_{\text {ind }}=\frac{[(1200+600) / 1057.9071]^{0.7191}-1}{0.0 .7191 * 0.28462}=2.27 \quad \geq-3 \text { and } \leq 3 \quad \text { (LMS z-score) }
$$

## Centiles and $z$-scores for length and head circumference velocities conditional on age

The centiles were calculated as follows:

$$
C_{100 \alpha}(t)=M(t)\left[1+L(t) S(t) Z_{\alpha}\right]^{1 / L(t)}, \quad-3 \leq Z_{\alpha} \leq 3
$$

The following procedure is recommended to calculate a z-score for an individual child with length or head circumference increment $y$ at the visit age $t$ :

1. Calculate

$$
z_{\text {ind }}=\frac{[y / M(t)]^{L(t)}-1}{S(t) L(t)}
$$

2. Compute the final $z$-score $\left(z_{\text {ind }}^{*}\right)$ of the child for that indicator as:

$$
z_{\text {ind }}^{*}=\left\{\begin{array}{ccc}
z_{\text {ind }} & \text { if } & \left|z_{\text {ind }}\right| \leq 3 \\
3+\left(\frac{y-S D 3 p o s}{S D 23 p o s}\right) & \text { if } & z_{\text {ind }}>3 \\
-3+\left(\frac{y-S D 3 n e g}{S D 23 n e g}\right) & \text { if } & z_{\text {ind }}<-3
\end{array}\right.
$$

where
SD3pos is the cut-off +3 SD calculated at $t$ by the LMS method:

$$
S D 3 \text { pos }=M(t)[1+L(t) * S(t) *(3)]^{1 / L(t)} ;
$$

SD3neg is the cut-off-3 SD calculated at $t$ by the LMS method:

$$
\text { SD3neg }=M(t)[1+L(t) * S(t) *(-3)]^{1 / L(t)} ;
$$

SD23pos is the difference between the cut-offs +3 SD and +2 SD calculated at $t$ by the LMS method:

$$
S D 23 \operatorname{pos}=M(t)[1+L(t) * S(t) *(3)]^{1 / L(t)}-M(t)\left[1+L(t)^{*} S(t) *(2)\right]^{1 / L(t)} ;
$$

and SD23neg is the difference between the cut-offs -2 SD and -3 SD calculated at $t$ by the LMS method:

$$
\text { SD23neg }=M(t)[1+L(t) * S(t) *(-2)]^{1 / L(t)}-M(t)[1+L(t) * S(t) *(-3)]^{1 / L(t)}
$$

To illustrate the procedure, examples with the 3-month interval length velocity conditional on age for girls follow.

Child 1: 12-month-old girl with an increment, i.e. length gain 7.5 cm between 9 and 12 months.
$\mathrm{L}=0.8538 ; \quad \mathrm{M}=3.8692 ; \quad \mathrm{S}=0.23503$;

$$
\begin{aligned}
& z_{\text {ind }}=\frac{[7.5 / 3.8692]^{0.8538}-1}{0.23503 * 0.8538}=3.79>3 \\
& S D 3 \text { pos }=3.8692 *[1+0.8538 * 0.23503 *(3)]^{1 / 0.8538}=6.72 \\
& S D 2 \text { pos }=3.8692 *[1+0.8538 * 0.23503 *(2)]^{1 / 0.8538}=5.74 \\
& S D 23 \text { pos }=6.72-5.74=0.98 \\
& \Rightarrow \quad z_{\text {ind }}^{*}=3+\left(\frac{7.5-6.72}{0.98}\right)=3.80
\end{aligned}
$$

Child 2: 18-month-old girl with an increment of 0.5 cm between 15 and 18 months.
$\mathrm{L}=0.8538 ; \quad \mathrm{M}=3.2051 ; \quad \mathrm{S}=0.28388 ;$

$$
\begin{aligned}
& z_{\text {ind }}=\frac{[0.5 / 3.2051]^{0.8538}-1}{0.28388 * 0.8538}=-3.28<-3 \\
& S D 2 n e g=3.2051 *[1+0.8538 * 0.28388 *(-2)]^{1 / 0.8538}=1.47 \\
& S D 3 n e g=3.2051 *[1+0.8538 * 0.28388 *(-3)]^{1 / 0.8538}=0.70 \\
& S D 23 \text { neg }=1.47-0.70=0.77
\end{aligned}
$$

$$
\Rightarrow \quad z_{\text {ind }}^{*}=-3+\left(\frac{0.5-0.70}{0.77}\right)=-3.26
$$

Child 3: 6-month-old girl with a length gain of 8.0 cm between 3 and 6 months.
$\mathrm{L}=0.8538 ; \quad \mathrm{M}=5.9428 ; \quad \mathrm{S}=0.17798$;

$$
z_{\text {ind }}=\frac{[8.0 / 5.9428]^{0.8538}-1}{0.17798 * 0.8538}=1.90 \quad \geq-3 \text { and } \leq 3 \quad(\text { LMS z-score })
$$

## 7. DISCUSSION

The intrinsic biological complexity of the dynamics of human growth made the construction of the standards presented in this report more challenging than was the case for the attained growth standards (WHO Multicentre Growth Reference Study Group, 2006a; 2007). This section seeks to provide guidance for the use and interpretation of the standards based on insights gained during construction of the velocity standards and feedback from clinicians who participated in reviewing and field-testing the velocity tools.

The standards are presented for the age span birth to 24 months. They include weight, length and head circumference centiles conditional on age, in variable measurement intervals. Additionally for weight, empirical centiles of velocity in 1- or 2-week intervals from birth to 60 days are presented. With the exception of tables 15 and 17 (velocity in g/d), all velocity tools of the WHO Child Growth Standards are increment standards describing the distribution of growth increments over variable intervals. As is the case for attained growth, the standards presented in this report are sex-specific. Appendix B summarizes specifications of the BCPE models for each of the growth velocity standards.

## Velocity conditional on age

The overall pattern of the (age-conditioned) centiles depicts the age-dependent changes in velocity that characterize human postnatal growth. Growth progresses at a rapidly decelerating rate from birth, reaching a near-plateau by the end of the first year and continues to taper off gently through the second year. This is the expected overall pattern of growth under conditions of adequate nutrition and psychosocial care with no chronic infections or unusual rates and/or severity of acute infections: the pattern that underpins the general expectation that infants will double their weight by age 6 months and triple it by 12 months. However, examination of individual growth trajectories has shown saltatory increments in short ( $\leq 24$ hours) intervals followed by periods (2-63 days) of no measurable growth (Lampl et al., 1992). Although the intervals ( 1 - to 6 -months) presented for the main age-conditioned tools of these standards cannot capture the short-span saltation and stasis described by Lampl and coworkers, the growth velocities of individual children in the WHO standards are characterized by very high variability in consecutive growth intervals. It is not unusual for a child to grow at the $95^{\text {th }}$ velocity centile one month and at the $20^{\text {th }}$ the next while continuing to track on the attained weight-for-age chart. Alternating or irregular patterns of high and low velocities may occur in successive periods even in the absence of morbidity. With regard to weight, losses or slow gains (related to morbidity or otherwise) in a given period are normally followed by higher velocities, likely indicating catch-up growth.

The 1-, 2-, 3-, 4- and 6-month increment tables are independent of each other and the clinician should use the one that most closely approximates the interval over which the child is seen. For example, the centile corresponding to an increment between age 2 and 3 months is not associated with the centile corresponding to half of the increment in the 2 -month interval between ages 1 and 3 months. This is because one cannot expect the growth rate in a given 2-month period, except perhaps at the median, to be the sum of the two corresponding 1 -month intervals.

With specific reference to weight, negative increments occur generally after 6 months of age and are captured in the lowest centiles. They coincide with the weaning period, when children are more exposed to food contamination, and when they become more active and start to explore their environment. Others who have developed velocity references have observed similar losses (WHO Working Group on Infant Growth, 1994), even if final published figures did not include them since only a narrow range of centiles were presented (Guo et al., 1991; Roche et al., 1989). It is important to note that losses that are tolerable in short intervals might not be acceptable in longer intervals. For example, the $5^{\text {th }}$ centile indicates a loss of about 100 g between 10 and 11 months and also between 11 and 12 months (Table 4), which can be acceptable for 1-month intervals at that age. However, the
same $5^{\text {th }}$ centile for a 2-month interval at the same age ( 10 to 12 months) indicates a gain of about 30 g (Table 6), implying that there was time for recovery within the longer interval.

## Alternative approaches to constructing conditional weight gain references

Others have approached the construction of conditional weight gain references by applying methodologies that adjust not only for age but also for regression to the mean (Wright et al, 1994; Cole, 1995; Cole, 1997). The theoretical basis for this approach is the expectation that over time infant weights drift towards the median from the tails of the distribution. Using this approach, weight gain is calculated in terms of the change (compared with the initial measurement) in the infant's attained weight SD score adjusted for regression to the mean (Cole, 1995). The formula for this calculation hinges on the correlation between the initial and second SD scores, which determines the expected slope of the change in the child's size between the two points of measurement. Despite its theoretical advantages, calculation of this conditional gain SD score requires computerization and thus limits the potential for its application. In effect, this approach has not gained currency in clinical settings.

To explore how conditional gain SD scores compare with the increment centiles presented in this report, the published methodology (Cole, 1995) was applied for adjusting for regression to the mean on 1- and 2-month interval weight increments (results are presented in Appendix C). The first step was to calculate the attained weight-for-age (WA) z-score for each child at each of the visits. Next, the respective correlation matrices for the 1- and 2-month intervals were derived. Then, the published formula to calculate $\mathrm{SD}_{\text {gain }}$ (the z -score associated with the change in WA z-score between visits) was applied. The $\mathrm{SD}_{\text {gain }}$ values were compared with z-scores of the age-conditioned 1-and 2-month weight increments.

Plots of empirical densities showed that the distributions of the z -scores from the two methods overlap for each respective test interval (figures C 1 and C 2 ). Distributions of pairwise differences between the z-scores from the two methods were also examined (figures C3 and C4). Ninety percent of the differences were between -0.33 and +0.34 (for 1 -month intervals) and between -0.27 and +0.29 (for 2-month intervals).

To assess the magnitude of the impact of regression to the mean, two sets of children were selected: one in the lower bound (WA z-scores between -2.5 and -1.5 ) and the other in the upper bound (WA z-scores between +1.5 to +2.5 ) of attained growth at the start (time1) of specified intervals. The change in their $z$-scores at the end (time 2 ) of 1- or 2-month periods were examined to observe what proportion deviated from the assumption of regression to the mean (Table C1).

For the lower bound (time1 z-scores between -2.5 and -1.5 ), the results were consistent with regression to the mean only for initial ages $0-1$ months and 0-2 months, i.e. WA drifted further from the median for $21 \%$ and $13 \%$ of children, respectively. For the remaining ages, $30-52 \%$ ( $1-$ month intervals) and $28-47 \%$ ( 2 -month intervals) of weights shifted further from the mean, contrary to shifts that would have reflected regression to the mean. Similar findings were observed for the upper bound (timel zscores between +1.5 and +2.5 ) i.e. $27 \%$ (age $0-1$ month) and $20 \%$ (age $0-2$ months) drifted away from the mean. In the older age groups, this tendency was observed for 37-55\% (1-month intervals) and $30-54 \%$ (2-month intervals). As expected, corresponding average changes in WA z-scores were, relatively high at ages $0-1$ or $0-2$ months (in the assumed direction of regression to the mean), but they dropped rapidly thereafter to near 0 .

In summary, growth in snapshots of 1- or 2-month intervals was consistent with regression to the mean between birth and 1 or 2 months but the phenomenon was much less evident at later ages. Differences between individual z-scores when applying the two methods were relatively minor. This
raises questions regarding the impact those differences have on clinical management and the method's conceptual and practical accessibility for users in disparate settings. For the age period when the largest impact of regression to the mean is observed, as described below this report provides sexspecific centiles for weight increments conditional on birth weight in 1- and 2-week intervals from birth to 2 months.

## Tables of weight velocity from birth to 60 days

These tables present physiological weight losses that occur in the early postnatal period but that are not usually included in available reference data.

In-depth comparisons between the sexes were made in the process of deriving these centiles. In most cases, boys' net increments in the 2-week intervals between 14 and 60 days were higher than girls' increments by values of $50-100 \mathrm{~g}$. The differences in the first two weeks (birth to 7 and $7-14$ days) were less clear-cut, but it was interesting to observe that the weight losses (depicted in the $5^{\text {th }}$ and $10^{\text {th }}$ centiles) between birth and day 7 were slightly attenuated in girls compared to boys.

It was not possible to estimate from these data precisely when infants should recover their birth weight following weight loss that is common in the first few postnatal days. Net increments at the median ( 0 to 7 days) are positive for both boys and girls, suggesting that recovery of birth weight could be achieved in less than one week. Considering the $25^{\text {th }}$ centile ( 0 g increment from birth to 7 days), the data suggest that $75 \%$ of newborns recover their birth weight by day 7 . It is understood that recovery depends on what percentage of birth weight was lost and successful initiation of lactation. However, rather than focus only on weight gain, it is important to adopt a holistic approach by looking at the child's overall health status and clinical signs. This involves also assessing mother-child interaction, indicators of successful breastfeeding such as infant breastfeeding behaviour and the timing of stage II lactogenesis (i.e. the onset of a copious milk supply), and breastfeeding technique (position and attachment), as these are necessary for maintaining successful infant nutrition. The overall breastfeeding profile and some aspects of its initiation among the infants included in these standards were published elsewhere (WHO Multicentre Growth Reference Study Group, 2006d).

The complexity of growth velocity is not adequately reflected in the usual presentation of gross estimations of growth rate over wide age spans. Such estimations overlook the dramatic changes that characterize growth in the first few months and the high variability within an individual child's growth rate in succeeding intervals. These centiles (birth to 60 days) provide a description of weekly and biweekly changes in velocity, illustrating the inadequacy of rules of thumb such as "infants should gain $200 \mathrm{~g} /$ week or $30 \mathrm{~g} / \mathrm{d}$ in the first 3 months".

Centiles are presented both for net increments and for velocity in $\mathrm{g} / \mathrm{d}$. It is important to note that the $\mathrm{g} / \mathrm{d}$ figures are not the simple average of the gross gains or losses reported in corresponding weekly and fortnightly tables. The $\mathrm{g} / \mathrm{d}$ figures are derived by calculating individual daily increments for newborns in each of the birth weight categories and then estimating centiles directly from the raw $\mathrm{g} / \mathrm{d}$ values. When mother-child dyads experience breastfeeding difficulties in the early postpartum period, lactation performance and weight gain are monitored every few days, hence increments per day are likely to be handier to use than weekly or fortnightly increments. Even in the absence of such difficulties, visits to the clinic take place at random ages, and these daily increments offer a flexible option for evaluating growth over fractions of the tabulated time blocks. It is important to note that the $\mathrm{g} / \mathrm{d}$ figures, particularly in the first week, are composite figures reflecting, on average, losses followed by recovery.

Contrary to speculation that weight velocity would vary by birth weight, the centiles from the various birth-weight categories were very similar, leading to the conclusion that velocities can be collapsed into a single column. Low or high anthropometric values observed in the WHO standards represent the physiological extremes of normality among children in the absence of intrauterine growth problems. If this were not the case, a negative correlation between birth weight and early growth rate would have been more likely because postnatal catch-up and catch-down growth would have been observed.

## Minimum weight gain tables

Tables of weight gain conditional on starting weight were requested by users of the table of "expected minimum gains in weight" in community-based growth promotion programmes mainly in Central America (Griffiths et al., 1996; Griffiths and McGuire, 2005). The AIN (Atención Integral al Niño) tables were developed using data from 112 children born between 1972 and 1974 and followed from birth to 2 years by the Centro Latinoamericano de Perinatología (Martell et al., 1981). The values of expected weight do not take into account sex or age, and it appears that the weight gain selected as the minimum was the $25^{\text {th }}$ centile; otherwise, little is known about them (Martorell et al., 2002). The original AIN table provides single values of expected minimum weight gains in 30-day or 60-day intervals relative to the child's starting weight.

Tables of 1- and 2-month weight gains conditional on starting weight were produced and circulated for peer review. Reviewers rejected them on substantive grounds, and they were thus excluded from the final standards.

Firstly, the basic assumption of the AIN table, i.e. that young children of the same weight grow at the same rate irrespective of age, is flawed. In the WHO standards, starting at 5 kg , there is a significant negative association between age and final weight. This implies that younger children at the same starting weight end up with a higher final weight after 1- and 2-month intervals compared to those at older ages.

Secondly, it is impossible to select "expected minimum weight gains" that would be appropriate for all infants or children with the same starting weight. Such values are bound to be too low for some infants/children and too high for others of the same starting weight. Moreover, the selection of single minimum thresholds introduces the notion of centile tracking in velocity that is contrary to normal physiological growth in individual children. In the WHO standards, the probability of two consecutive 1 -month or 2 -month weight increments falling below the $5^{\text {th }}$ centile is $0.3 \%$. If the $15^{\text {th }}$ centile is chosen, this probability increases to only $2 \%$ and $1.8 \%$, respectively.

Thirdly, as infants grow older the lower centile values ( $25^{\text {th }}$ and below) become less than the day-today variability in weight, making detection of a minimum weight at this level impossible. Examining the 1 -month interval centiles for boys, for starting weights greater than about 8.5 kg , the $25^{\text {th }}$ centile value for final weight is only 100 g greater than the starting weight. The day-to-day variability (SD) is about twice this level. For girls, 100 g differences are seen between starting and $25^{\text {th }}$ centile final weights at even lower weights, e.g. about 8 kg . For girls that start at 12.7 kg , the $25^{\text {th }}$ centile final weight is 100 g less than the starting weight. The situation is even worse if the $15^{\text {th }}$ or $5^{\text {th }}$ centiles are selected (e.g. examining the 1 -month interval for girls, a starting weight of 12 kg implies a loss of 100 g and 200 g in the final weight for the $15^{\text {th }}$ and $5^{\text {th }}$ centile, respectively).

## Overall considerations

Measurement error. Measurements of growth are subject to error from multiple sources. Faulty measurements can lead to grossly erroneous judgements regarding a child's growth. The accuracy of growth assessment is improved greatly if measurements are replicated independently and the values
averaged. This procedure minimizes the impact of faulty single measurements. MGRS measurements were undertaken to assure the highest level of reliability; and the final values used in the creation of these standards were an average of two observations, thereby minimizing random measurement errors in observed growth. This level of reliability is not typical in routine clinical measurement in primary health care settings; however, it can be achieved in research contexts (WHO Multicentre Growth Reference Study Group, 2006b) and where resources permit, in clinical situations caring for children at high risk of growth problems. The training course on child growth assessment is a tool to assist health care providers in the effective application of the WHO growth standards. It teaches, inter alia, the knowledge and skills needed to measure children correctly (WHO, 2008).

Measurement intervals in field application. Ideally, velocity assessment should be done at scheduled visits that coincide with the ages and intervals ( $1,2,3,4$ or 6 months) for which the centiles are presented. In practice, however, the timing of clinic visits is dictated by uncontrollable factors, and ingenuity will be called for in applying the standards. In constructing the standards, some variation was allowed around the intervals. For measurements made at ages $0-6$ months, $6-12$ months and 12-24 months, the allowable deviations from the exact planned age were $\pm 3$ days, $\pm 5$ days and $\pm 7$ days, respectively. The practical advantage of this approach is that use of the standards allows for equally slight deviations without a need to correct observed increments through interpolation. For example, to assess a two-month increment between 11 months and 13 months of age the observed increment could be validly used as long as the first measurement was no more than 5 days early or late and the second measurement no more than 7 days early or late.

The simplest approach to dealing with measurement intervals beyond allowable ranges is to interpolate (i.e. prorate) observed increments to the relevant interval or to refer to the next larger interval if appropriate. For example, a boy weighed at 11 months returns at 13 months and 24 days having gained 600 g . If this increment is prorated to the 2-month interval 11-13 months, the estimated gain is $429 \mathrm{~g}\left(600 \mathrm{~g} / 84\right.$ days $\times 60$ days), which is just below the $50^{\text {th }}$ centile ( 458 g , Table 6 ). If the 3-month interval 11-14 months is referred to instead, there is no need to interpolate as the visit falls within the allowable difference ( $\pm 7$ days); his increment $\left(600 \mathrm{~g}\right.$ ) also is just below the $50^{\text {th }}$ centile ( 665 g , Table 8). The assumption made is that the rate of growth was constant over this period, but there is no alternative way of partitioning the increment.

If the observed interval is on target, say exactly 2 months, but the starting and ending ages do not coincide with those tabulated in the standards (e.g. an increment measured over the exact 2 -month interval between 11.4 and 13.4 months of age), the recommended practical solution is to use the tabulated reference values for the 11 to 13 -month age interval. Similarly, for an increment observed between 11.6 and 13.6 months of age one would use the reference values tabulated for the 12 to 14 -month interval. It should be understood that these are compromises whose limitations are especially apparent in the first year when growth decelerates rapidly and the difference in velocity between consecutive periods can be large. For example, growth between 2.5 to 3.5 months carries equal contributions from 2-3 and 3-4 month intervals: a baby girl who gained 310 g would be classified as below the $3^{\text {rd }}$ centile at 2-3 months and as below the $15^{\text {th }}$ centile at $3-4$ months. The best clinical judgement in such circumstances requires making a holistic assessment of the child's health. A more precise option in the forgoing case (i.e. when interval length is on target) is to interpolate the L, M and S values from consecutive age intervals and to calculate the child's z -score as described in Chapter 6.

Clinical usefulness of growth velocity. The questions that a clinician seeks to answer when using a velocity standard include whether a child's growth rate over a specified interval, or over a series of intervals, raises concern about underlying morbidity; or in the context of interventions to promote growth (e.g. in endocrinology), whether a given treatment produced the expected change in growth rate; or, for the newborn, if breastfeeding has been successfully established.

There are some fundamental differences between velocity and attained (distance) growth that affect how the increment standards should be used and interpreted. Chief among them is the lack of correlation between successive increments in healthy, normally growing children. For individual attained growth curves, the variability in successive z -scores tends to be minimal over short periods (there are high correlations between successive attained values). This "tracking" is not usually seen for successive individual growth velocities. For example, as indicated earlier, the probability of two consecutive 1 -month or 2 -month weight increments falling below the $5^{\text {th }}$ centile is $0.3 \%$. If the $15^{\text {th }}$ centile is chosen, this probability increases to only $2 \%$ and $1.8 \%$, respectively. Normally growing children can have a very high $z$-score one month and a very low one the following month, or vice versa, without any underlying reason for concern. Thus, a single low value is uninformative; only when velocities are repeatedly low should they cause concern. Nevertheless, very low z-score values, even if observed only once, should raise the question of whether there is underlying morbidity within the holistic clinical assessment of the child.

Some authors recommend that two successive increments below a cut-off like the $5^{\text {th }}$ centile be used (Roche and Sun, 2003). Others suggest that consecutive increments below the $25^{\text {th }}$ centile should signal growth problems (Healy et al., 1988). Healy and co-workers chose this limit on the basis that the chance of a false positive diagnosis (i.e. a normally growing child with two successive increments below this centile) is approximately $6.25 \%\left(0.25^{2}\right)$. This raises an important question: Does the interval matter, for example, if these low velocities occur in two consecutive 1-month versus 3-month intervals? We think it does when we consider the cumulative effect of growth deficits. Future research will need to determine what patterns of successive velocity thresholds over which specified intervals have the best diagnostic and prognostic validity for specific diseases. The need for this type of clinical research applies to both high and low velocities.

During periods of severe illness (e.g. prolonged diarrhoea), one would expect very low velocity followed by compensatory high velocity (catch-up). During catch-up growth, one would expect successive increments to be repeatedly in the higher ranges. An important difference with attained growth is that single extreme values of increments are comparatively less worrisome. For example, $z$-scores above +6 and below -6 for attained growth are observed only in very rare conditions like severe dwarfism, gigantism, severe cachexia and extreme obesity. However, such extreme z-score values may be seen during the assessment of growth velocity. Ultimately, growth velocity must always be interpreted in conjunction with attained growth, as the position on the attained growth chart is essential to interpreting the growth rate, e.g., low weight velocity if the child is overweight and catching down, or higher weight velocity reflecting catch-up growth when recovering from illness.
