HUMAN MONKEYPOX
1970-1979

by

J. G. Breman,[1] Kalisa-Ruti,[2] M. V. Steniowski,[3] E. Zanotto,[3] A. I. Gromyko[1] and I. Arita[1]

ABSTRACT

With the eradication of smallpox throughout the world increasing attention has been given to human monkeypox. This disease, first described in central Africa in 1970, resembles smallpox clinically but differs epidemiologically. Forty-seven cases of human monkeypox have occurred since 1970 in five central and western African countries; Zaire has reported 38 cases. The evolution of the illness and the sequelae of monkeypox and severe smallpox are the same; monkeypox has a case fatality rate of 17%. Smallpox vaccination protects against monkeypox. All cases have occurred in the tropical rainforest. Children below 10 years of age comprise 83% of cases. Case clusters have been observed in certain zones within countries and within families. Person-to-person spread has possibly occurred four times; the secondary attack rate among susceptible very close family members was 7.5% (3 cases/40 contacts) and among all susceptible contacts was 3.3% (4 cases/123 contacts). This is much lower than occurs with smallpox which is between 25-40%. The low transmissibility, coupled with the low frequency of disease, indicates that monkeypox is not a public health problem; however, more data are needed.

While many animals near human monkeypox cases have orthopoxvirus antibodies, the natural reservoir and vector of monkeypox virus is unknown. Studies are in progress to identify the natural cycle of monkeypox virus and to define better the clinical and epidemiological features of this disease.

Introduction

The last case of endemic smallpox was reported in Somalia in October 1977. A World Health Organization Global Commission certified the global eradication of smallpox in December 1979 and this decision will be presented to the World Health Assembly in May 1980 for final approval. Accordingly, most countries have stopped vaccination and others are expected to stop soon. Since immunity levels in the population will soon decline rapidly, it is extremely important that diseases resembling smallpox be carefully evaluated. Such investigations are essential to provide continuing assurance to health officials and the public alike that smallpox has indeed been eradicated and that continuing vaccination is no longer necessary. They will help to define further those diseases which, although bearing a clinical resemblance to smallpox, may differ in important epidemiological features.

The most important of these diseases is human monkeypox, which was first detected in the Basankusu district, Equateur region, Zaire (formerly the Democratic Republic of the Congo) in 1970, two years after the last case of smallpox had occurred in the area.[1,2] Some features of the first 21 human monkeypox cases have been reviewed.[1-5] It is the purpose of this report to describe the clinical and epidemiological features of all 47 cases of human monkeypox reported from 1970 through 1979.

Clinical features

The major clinical features of human monkeypox are similar to those of smallpox. There is a two to four day prodromal illness with fever and prostration. The eruption then begins. As with smallpox, the lesions develop more or less simultaneously and evolve together at the same rate through papules, vesicles and pustules before umbilicating, drying and desquamating. This process usually takes about two to four weeks, depending on the severity of the disease. The distribution of the rash is mainly peripheral. Severe eruptions can cover the entire body (Photos 1-6), including the palms and soles. Six of the 47 cases (13%) had a mild illness (less than 25 lesions with no incapacity, not usually requiring medical care), 19 (40%) had moderate disease (more than 25 lesions, necessitating stopping most physical activity, usually requiring medical care) and 22 (47%) had severe disease (more than 100 lesions, severely incapacitated, requiring medical care (Table 1).

Most skin lesions are about 0.5 cm in diameter but some up to 1 cm have been seen. Lesions have been noted on the mucous membranes, the tongue and genitalia (Photos 4, 6). Lymphadenopathy, especially in the neck (submandibular and cervical) and inguinal areas, was particularly prominent in 17 cases (Photos 4, 5).

Pitting scars develop, are most often on the face, and diminish with time. Secondary infection of the lesions is common and this may play a role in scarring. About half of the scars from lesions seen initially on the face and body were detectable one to four years after the acute illness. Desquamation of crusts leaves areas of hypopigmentation. Hyperpigmentation follows after a few months and diminishes with time (Photo 7). In some cases large shallow residual scars are seen. In one case a primary corneal lesion caused unilateral blindness (Photo 7). Another patient who was vaccinated several years previously developed only one lesion (Photo 9) further emphasizing that some cases can be exceedingly mild and may go unreported.

Only four of the 47 patients (9%) had a vaccination scar. These were persons, ages 35, 30, 24 and eight years, who were vaccinated more than five years previously.

Eight (17%) of the patients died from monkeypox during the acute illness. They were between seven months and seven years of age. None had been previously vaccinated. Three other patients died of other causes two months, four months and 15 months respectively after their illness.

Comparatively few laboratory tests have been done on these patients. This is because there are often major delays in reaching the patient after notification, difficulties in collecting scrapings from lesions or obtaining serum and problems in procuring follow-up samples.

Table 2 gives virological and serological test results. For the 47 patients, monkeypox virus isolation confirmed the diagnosis in 30 among 40 patients from whom skin scrapings were taken. Of the remaining 17 patients, seven had poxvirus particles seen on electron microscopic (EM) examination of skin samples, but no virus could be isolated. Ten others had serological as well as clinical and epidemiological evidence for monkeypox infection; skin specimens were not collected from seven of these patients and another specimen was not suitable for testing.

The virus could be isolated from specimens taken up to 18 days after onset of the rash. A specimen from one patient (case 19) which was EM negative, was positive for monkeypox virus upon culture. The precipitation-in-gel test was less helpful than other virological methods.

Serological tests confirmed a previous orthopoxvirus infection in 34 of 35 patients tested (Table 2). The fluorescent antibody test[6] and radioimmune assay examination[7] identified monkeypox antibodies in sera from 19 of the cases. One of these patients was negative by virological tests and skin samples could not be collected from four others.

In an attempt to detect specific immunological defects, IgG and IgM were quantitated for six patients, using a radio-immunoassay technique. All monkeypox cases had elevated IgG and some were markedly increased; three cases had increased IgM. This may only reflect the consequences of parasitic, bacterial and viral infections to which these patients are exposed.

Epidemiology

Where

Cases have been detected in five countries: Zaire (38), Liberia (four), Nigeria (three), Ivory Coast (one) and Sierra Leone (one). One recent case, number 39, originating in Nigeria, was detected in Benin. All 47 cases have occurred in the tropical rainforest of western and central Africa, between 8° south and 8° north latitude, where hunting of wild animals for food is common (Figures 1, 2). All but two of the cases have lived in villages of about 200 to 1000 persons. One of these two cases (case 18) ate meat originating from the tropical rainforest before disease onset and the other (case 47) is under investigation.

When

The cases have occurred sporadically since August 1970. Six cases were reported in 1970, three in 1971, five in 1972, three in 1973, one in 1974, two in 1975, three in 1976, six in 1977, 12 in 1978 and six in 1979.

Cases occurred most often in the dry season although they are reported throughout the year (Figure 3). Twenty of the 38 cases in Zaire had onset of rash between January and March.

Who

Children were affected more frequently than adults. The mean age of patients was eight years (range seven months to 35 years); the median was four years. Thirty-nine of the 47 cases (83%) were below 10 years; 25 (55%) were below five years and five were below one year. Twenty-six patients were male and 21 were female. However, among patients older than 15 years, five of seven were women.

Clustering of cases

Clustering of patients in countries, in localities within countries and within families has been observed (Figures 1, 2). Three of four cases in Liberia (2, 3, 4) lived in one village as did two of the three patients in Nigeria.

In Zaire, the north-western Equateur region, one of nine regions, has reported 21 of 38 cases (55%). Within this region 13 of the 21 cases (62%) have been reported from the Bumba zone, one of 21 zones in the Equateur region. Kasai Oriental region has reported nine cases; eight came from the Kolé zone, one of 12 zones in this region. Seven were detected in Bandundu region and four of these were in the Popokabaka zone.

There have been five instances in which presumed co-primary cases occurred in the same family (cases 2-3, 11-12, 26-27, 32-33, 37-38). Case number four lived next door to one of these families (cases 2, 3). The interval between onset of illness was less than 24 hours for one case, one day for two cases, two days for one case, three days for one case and five days for one case; the latter patient (case 38) developed a rash seven days after the co-primary, case 37.

Person-to-person spread

In four families, the onset of rash of second cases occurred nine, 12, 15 and 17 days respectively after the first case (Table 3). These cases may have been infected from a common source or secondary transmission may have occurred. Three of the four index patients had severe disease and the fourth had moderate disease. The disease in secondary cases was milder than the primary case in two instances and in two episodes the secondary cases were of comparable severity. All of the index and secondary cases were unvaccinated. No cases of possible tertiary spread were found.

If it is assumed that all four cases represented person-to-person spread of monkeypox, the potential for transmission may be assessed by relating the number of cases to the total of susceptibles (those without a vaccination scar) among family and other close contacts. In this setting the contacts had a vaccination scar rate of 70% or more.

Within immediate family members (parents, siblings, children or spouse), the secondary attack rate among susceptibles was 7.5% (3/40) (Table 4); susceptible siblings of monkeypox cases had a 10% attack rate (2/20). Among all other persons having known face-to-face contacts with patients, including more distant relatives, the secondary attack rate among susceptibles was 1.2% (1/83). When all known susceptible contacts are included the secondary attack rate is 3.3% (4/123). This secondary attack rate is low compared to smallpox which is about 25-40%.[8,9]

Surveillance for monkeypox

Human

In 1975, special vaccination scar and facial pockmark surveys were conducted among populations living near where human monkeypox cases had occurred during the previous four to five years in the Ivory Coast, Nigeria and Sierra Leone. Immunity levels were comparatively low in younger age-groups. Fifty-seven per cent. of 2125 children 0-4 years, and 29% of 8047 school-age children had no vaccination scars, indicating their probable susceptibility to monkeypox infection. In those areas, there was no evidence of other cases of monkeypox (or smallpox) as determined by surveys of facial pockmarks or by records at health units in the area.

From 1975 to 1977 additional facial pockmark surveys were conducted in western and central Africa to detect possible cases of smallpox and thus evidence of continuing transmission. Over 6 500 000 children of school age and younger were seen; 1 825 380 were of preschool age. None had facial pockmarks suggestive of smallpox or monkeypox other than for cases known previously.[10]

Data from smallpox vaccination scar surveys done in 1978 and 1979 in villages where cases occurred and in surrounding villages are shown in Table 5. Less than one half of the children from 0-4 were vaccinated in villages where cases occurred and about 60% of this age-group was found vaccinated in nearby villages. The area in Nigeria where case number 39 occurred had substantially less vaccination coverage than in Zaire. In some areas of the Bumba zone over 90% of children less than 15 have smallpox vaccination scars as do virtually all adults, due to repeated vaccination associated with investigation of monkeypox cases.

During the past 10 years, 1652 specimens have been collected from patients with febrile eruptive disease in western and central Africa to confirm or rule out smallpox or monkeypox infection (Table 6). Some specimens were collected in preparation for visits of International Commissions to certify freedom from smallpox. Zaire has submitted 74% of these specimens and has reported 81% of the cases.

Since 1971 Zaire has had 14 surveillance teams in the field responsible for promoting surveillance, including distribution of specimen collection kits to health units. This accounts in part for the relatively large number of specimens taken. A widely publicized reward of about US$ 40 is given to persons who report a confirmed monkeypox case. All but two of the monkeypox cases were detected and reported by the fixed health units. Two cases were found in Bumba zone by active surveillance in villages near known foci of monkeypox.

Within Zaire there has been variation in specimen collection activities in the regions (Table 7). The Equateur and Haut-Zaire regions have together submitted over 52% of the specimens. However, 21 of the 38 cases occurred in Equateur and none in Haut-Zaire. The ratio of monkeypox cases to specimens collected is highest in Kasai Oriental (one in eight). Roughly 40% of the African tropical rainforest is in Zaire. No cases have been found outside of rainforest areas in Zaire or elsewhere.

Animal

Although cases and outbreaks of monkeypox infections have occurred among non-human primates and other animals in laboratories and zoos in Europe and North America, no such cases have been detected in nature. Thus the source of human monkeypox infections is still unknown.[11] Epidemiological studies have suggested monkeys and/or rodents as a possible source but, until recently, only a small number of specimens for viral culture have been obtained. Earlier serological studies showed a low prevalence of orthopoxvirus neutralizing antibodies in mammals captured in western and central Africa. In one survey, 10 of 372 sera were positive;[3] seven were from non-human primates (four chimpanzees from Sierra Leone, two monkeys from the Ivory Coast, and one monkey from Liberia). Another sero survey failed to detect significant antibody in over 2000 sera taken from Asian and African non-human primates, although none of these animals is known to come from areas near human monkeypox cases.[12] However, recent surveys conducted in areas where human monkeypox cases have occurred have shown a 23% (50/215) prevalence of poxvirus neutralizing antibodies in non-human primates.[4,13] A study done in Zaire near human monkeypox cases showed that 11 of 55 monkeys had neutralizing antibody.[14] Antibodies have also been found in rodents, other large mammals and birds in forest areas of the Ivory Coast[4] and in rodents in Zaire.[15] However, it has not been possible until recently to determine whether these antibodies had developed in response to monkeypox virus infection or to infection caused by any other orthopox virus species which might have infected mammals and birds. Recent work has shown that monkeys found near human monkeypox cases have monkeypox specific antibody.[6,13] These and further refined tests[7] will serve as valuable tools during current epidemiological studies underway in Zaire and others which are planned. Special ecological studies began in the Equateur region of Zaire in June 1979 and these results will be reported separately.

Although attempts to isolate monkeypox virus from animals captured near human monkeypox cases have failed, four whitepox virus strains have been identified in organs of animals captured in the wild near such cases. These "wild whitepox" strains came from kidney tissue of one chimpanzee (Pan troglodytes), one forest dwelling monkey (Cercopithecus ascanius) and two rodents (Heliosciurius rufobrachium, the sun squirrel; Mastomys natalensis, the multimammate rat) captured in Zaire.[16,17] Prior to these isolations two strains of whitepox virus had been previously isolated from routine Cynomolgus kidney cell cultures.[18,19] Whitepox virus cannot be distinguished from variola virus by current biological and chemical methods and, thus, these isolations are of special interest. These findings, however, must be interpreted with caution since it is not possible to conclusively rule out that these isolates might represent laboratory cross-contamination rather than primary isolations. Moreover, existing epidemiological evidence indicates that the virus causing

smallpox is not present in this area because (1) no human infections with a variola-like virus have occurred in Zaire during more than eight years since the last smallpox case occurred, and (2) it can be presumed that the surveillance system is sensitive enough to detect such cases, as many monkeypox cases have been found.

Discussion

Most cases of human monkeypox have a characteristic clinical appearance, with a two day prodrome and typical smallpox-like rash evolving over two to four weeks. Severe lymphadenopathy is more prominent among patients with monkeypox than those with smallpox. Six of 47 cases (13%) have been mild or very atypical, suggesting the possibility that unidentified cases may have occurred, especially in areas where surveillance is poor.

While clinical features cannot readily distinguish between smallpox and monkeypox, the epidemiological features are quite distinct. Human monkeypox is a sporadic infrequent disease detected in small villages in the tropical rainforest of central and western Africa. Only four episodes of possible secondary spread of human monkeypox have been recorded. The 7.5% inter-human transmission rate of monkeypox to susceptible close family members is much less than that for smallpox. This very limited avidity of monkeypox for humans indicates the virus is probably a zoonoses. In addition to these important epidemiological differences, monkeypox and variola virus, both orthopoxviruses, have distinct biological and genetic differences.[20,21]

The occurrence of human monkeypox in small villages in the moist rainforest of west and central Africa gives only general clues as to the source of this infection. The disease appears to be more frequent in the dry season, similar to that seen for smallpox. Whether this relates to a possible respiratory mode of transmission, as occurs with smallpox, is unknown. The geographical distribution may represent, in part, an artefact and may be a function of the sensitivity of surveillance and the number of specimens sent for analysis.

Most people in these areas have multiple contacts with a variety of wild animals. All cases have had contact with primates and almost all have had contacts with two or more other animals. Young, unvaccinated children and adult females seem to be at special risk; the former, perhaps, because they play with the carcasses of animals after the hunters return to the village and the latter because they are responsible for dressing and cooking the animals and may inoculate themselves during this procedure.

The incubation period of naturally transmitted human monkeypox is unknown, although experiments with monkeys infected by the parenteral route have shown an incubation period of 7 to 14 days resembling that of smallpox.[22] Based on evidence from the few cases who had only one or two animal contacts in the month preceding infection, the incubation time in humans may be about 12 days, similar to that observed in smallpox. Possible "secondary" cases were generally milder and atypical, if indeed they represented inter-human spread rather than primary infection from a common source. When the level of vaccination immunity decreases in Zaire and elsewhere in west and central Africa, a possible increase in cases of human monkeypox may occur, thus providing further information.

Although the natural source of human cases is still obscure, epidemiological and serological surveys suggest that certain animals (forest-dwelling monkeys, squirrel, porcupine or pangolin) may be involved in the natural cycle of transmission. Field studies will focus initially on these animals. Concurrently, serological techniques are being developed which will permit precise measurement of past infection with monkeypox and other orthopoxviruses. This will greatly aid epidemiological investigations of human and animal populations.

The finding of whitepox virus requires that, as for monkeypox, surveillance be maintained and specimens promptly collected and tested if monkeypox/smallpox-like disease occurs in the tropical rainforest. Laboratory analysis of these and similar strains is necessary for continued confirmation that there is no animal reservoir of variola virus and to monitor orthopoxviruses that might menace humans in the future.

Postscript

Monkeypox case 48: A 3 year old unvaccinated girl from the forest area of southern Cameroon developed a severe rash on 14 September 1979. Specimens were collected on 30 September. Due to special problems, monkeypox virus was not isolated from these specimens until January 1980. In February 1980 a complete field investigation was done by a joint team from the Cameroon Ministry of Health, the Organisation de Coordination pour la Lutte contre les Endémies en Afrique Centrale (OCEAC) and the World Health Organization. The team confirmed the diagnosis. No other human cases were detected. The child had contact with a dead squirrel about two weeks before the illness began. This is the first case of monkeypox reported from the Cameroon.

Acknowledgements

We are grateful to the many health workers and administrative authorities in Zaire and elsewhere in west and central Africa for their participation in monkeypox surveillance activities; to Dr J. H. Nakano and Dr S. S. Marennikova and their staff at, respectively, the Center for Disease Control, Atlanta, Georgia, United States of America and the Research Institute of Virus Preparations, Moscow, USSR for laboratory support; Dr A. H. Abou-Gareeb, Dr C. Algan, Dr J. Mahoney, Dr H. Ramamonjy-Ratrimo, and staff at the WHO Regional Office for Africa for technical and administrative support; to Dr F. Fenner (Centre for Resource and Environmental Studies, the Australian National University), Dr D. A. Henderson (Johns Hopkins University School of Hygiene and Public Health) and Dr J. Tulloch (WHO) for manuscript review; and to Miss C. Sands for help in preparation of the manuscript.

HUMAN MONKEYPOX
1970-1979

Photos 1-6: Seven-year old girl with monkeypox from Equateur region, Zaire, during day 8 of rash.

Photo 3: Old scar on arm, not due to vaccination.

Photo 4: Heavy concentration of lesions on the hands, inguinal lymphadenopathy and pustules on genitalia.

Photo 5: Swollen lower face and neck due to cervical and sub-mandibular and lymphadenopathy.

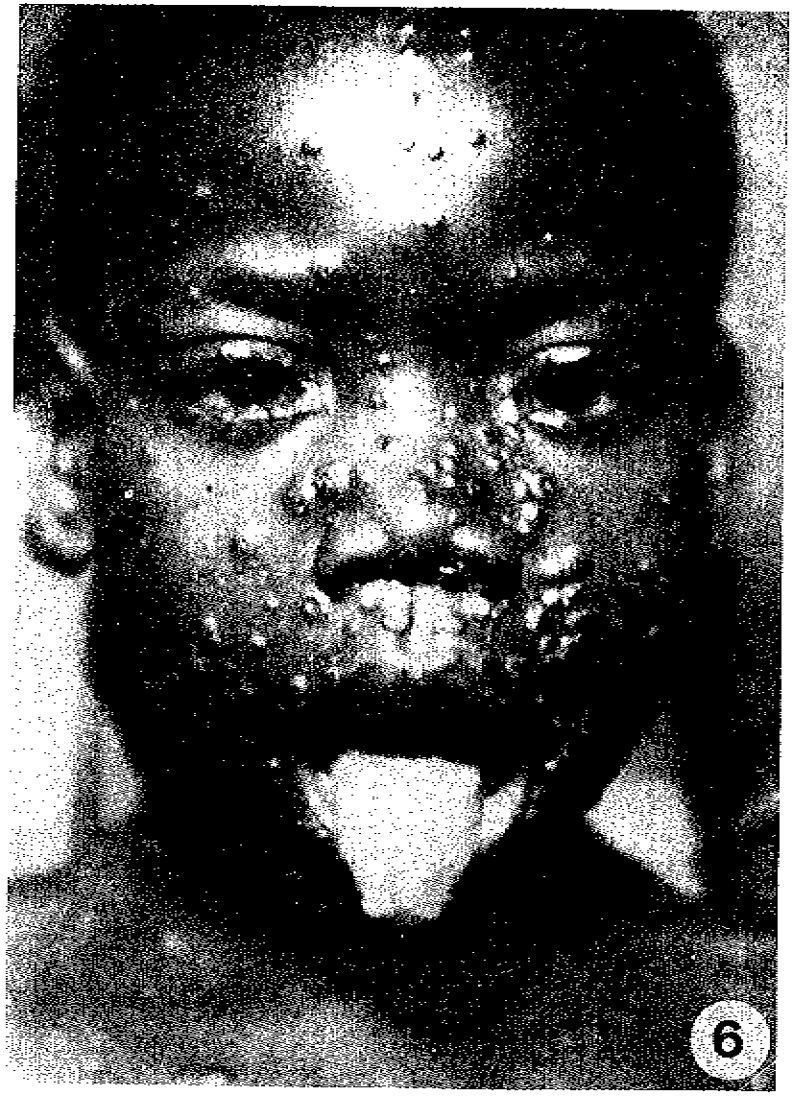

Photo 6: Lesions on lips, tongue and eyelid

Photo 7: Same patient 16 months after initial illness: hyperpigmentation of lesions with shallow, pitting scars most prominent over bridge of nose.

Photo 8: Eight year old boy with unilateral blindness following primary lesion on cornea; monkeypox occurred one year previously.

Photo 9: 0.5 mm pockmark in centre of upper lip in 35-year-old woman who had disease three months previously; this was the only lesion on patient who had been vaccinated more than 10 years before. Monkeypox virus was grown from the scab taken during the acute illness.
